A DICTIONARY OF APPLIED PHYSICS

EDITED BY SIR RICHARD GLAZEBROOK K.C.B., D.Sc., F.R.S.

IN FIVE VOLUMES
VOL. I
MECHANICS—ENGINEERING—HEAT

MACMILLAN AND CO., LIMITED
ST. MARTIN'S STREET, LONDON
1922
PREFACE

During the past twenty-five years the applications of Physics to Industry have
grown enormously. The National Physical Laboratory was opened in 1900, while
colleges and Technical Colleges have multiplied, and recent years have seen
the growth of the Department of Scientific and Industrial Research, with its
Associations in many fields, its studentships, and its skilled Research
Workers.

Meanwhile, the results of the labours of the past are, for the most part,
ttered in the Proceedings of learned Societies or stored in the brains of the
workers to whose efforts they are due.

To find out what are the latest methods of Calorimetry, what exactly is
own about the laws of Friction, how far has the theory of the Steam Engine
advanced, what are the principles on which methods of accurate gauging or of
a determination of the many factors which come into the lay-out of a big
etrical plant, the design of a Dynamo, or the methods of Pyrometry are based,
and a long search in Libraries and, not infrequently, a futile journey to some
where it is hoped the wished-for information may be found.

The Science of Aeronautics, the Design of Optical Instruments, the Methods
Metalurgy, the Construction of Clocks, Telescopes or Microscopes, the Laws
Music and Acoustics are all based on Physics.

The manufacturer who is concerned with those and, indeed, with countless
other subjects must know, not perhaps all that has been done—that would be
a heavy task—but where he may find the latest and most accurate informa-
on the subject with which he is mainly concerned. This it has been the
object of the Dictionary of Applied Physics to give. Applied Physics is a wide
subject and the task has been a heavy one.

The Dictionary will appear in five volumes of 800-1000 pages each, and, as
ill be seen from the names of some of the principal contributors, the Editor has
been fortunate in securing the help of those most competent to write on each
subject. His thanks are due, in the first place, to those colleagues, without whose
ardent help the Dictionary could not have been produced. He is also indebted
to a number of Scientific Societies whose Councils have allowed use of illus-
trations from their Proceedings to be freely made. Among these should be men-
tioned in particular the Royal Society, the Institution of Mechanical Engineer
and the Institution of Electrical Engineers. The same help has been readily afforded by a number of Publishers.

It is clear that, with so large a range of subjects, any individual worker will, probably, be concerned mainly with one branch, and, with this in view, the volumes have been arranged, as far as possible, in subjects. To obtain information as to the latest advances of Applied Electricity it will not be necessary to purchase the sections of the Dictionary dealing with Aeronautics or Meteorology. The arrangement in each volume is alphabetical, but, at the same time, it has been thought best to deal with each main subject—for example, the Thermodynamics of the Steam Engine—in a continuous article; references are given, each in its own alphabetical position, to the headings of the various sections of an article and to the more important subjects which it includes.

DICTIONARY OF APPLIED PHYSICS

ABSOLUTE SCALE OF TEMPERATURE—AIR METERS

--- A ---

**Absolute Scale of Temperature (Kelvin).**
If a perfectly reversible heat-engine takes in a quantity of heat \( Q_1 \) at temperature \( T_1 \) and rejects \( Q_2 \) at temperature \( T_2 \), then \( Q_1/T_1 = Q_2/T_2 \); provided the temperatures \( T_1 \) and \( T_2 \) are measured on the absolute thermodynamic scale. Hence the ratio of the temperatures on that scale is equal to the ratio of the heat taken in to the heat rejected by any perfectly reversible engine working between those temperatures. See "Thermodynamics," §§ (17), (22); "Engines, Thermodynamics of Internal Combustion," § (7).

**Absolute Zero, Definitions of, on "Gas" and "Work" Scales.** See "Thermodynamics," § (4).

**Absorption Dynamometers.** See "Dynamometers," § (2).

**Absorption of Radiation as Affecting the Readings of Radiant Pyrometers.** See "Pyrometry, Total Radiation," § (19).

**Absorption Pumps:** Fixed. See "Air-pumps," § (25).

**Achimére Ibach.** See "Kinematics of Machinery," § (4) (iv).

**Achimére, Hydraulics." See "Hydraulics," § (56).

**Adiabatic Change.** A change in the volume and pressure of a body carried out reversibly in such a way that no heat is allowed to pass to or from the body. See also "Thermodynamics," §§ (16), (38).

AIR-PUMPS

INTRODUCTION

(1) Compressors, Evacuators, Blowers.—An air- or gas-pump is a device whereby gas is transferred from a low-pressure vessel (L.P.V.) to a high-pressure vessel (H.P.V.). The term "vessel" includes the free atmosphere, and the term "gas" includes vapours. It is assumed, unless the contrary is stated, that the L.P.V. and H.P.V. are at the same temperature.

If the L.P.V. and H.P.V. are separated by a gas-tight partition, and if the gas is not a saturated vapour, the pump will diminish the pressure in the L.P.V. and increase it in the H.P.V.; it will act at the same time as a compressor and as an evacuator. In practice one of the two vessels is almost always maintained at atmospheric pressure, and variations of pressure in the other vessel alone are important. If this condition is fulfilled, a compressor may be defined as a pump of which the L.P.V. is at atmospheric pressure, an evacuator as one of which the H.P.V. is at atmospheric pressure.

The L.P.V. and H.P.V. are seldom completely separated, except in laboratory evacuators; there is a continual stream of gas from one to the other. If the energy required to produce this stream is comparable with the whole work done on the gas, the pump may be termed a "blower," or, if it is of one constructive type, a "fan." The distinction between pumps and blowers, though formally indefinite, is perfectly clear in practice. Blowers are usually, but not always, compressors, producing pressures greater than atmospheric. In blowers there can be no single and definite \( p_a \) or \( p_t \), capable of general scientific definition; but there is usually some pair of places along the stream of gas passing through the blower at which it is obviously convenient to measure \( p_a \) and \( p_t \). These places may be regarded for our purpose as constituting the H.P.V. and L.P.V.

(2) NOTATION.—Suffixes \( L \) and \( H \) denote quantities referring to the L.P.V. or H.P.V. Many of the formulae given will still be true if the suffixes \( L \) and \( H \) are interchanged; this feature is indicated by writing before them (" \( L \) or \( H \) ").

\[
P, \ P_L, \ P_H = \text{pressure}.
\]

\[
P_a = \text{initial pressure (the same for L.P.V. and H.P.V.)},
\]

\[
P_f, \ P_f^H = \text{final pressures}.
\]

\[
\alpha = \frac{P_f^H}{P_f} = \text{range}.
\]

\[
H = \text{atmospheric pressure}.
\]

\[
P_a = \text{vapour pressure}.
\]

\[
V_L, V_H = \text{volumes of L.P.V. and H.P.V.}
\]

\[
v_L, v_H = \text{maximum and minimum volumes of "cylinder."}
\]

\[
T_L, T_H, T_0 = \text{absolute temperature of atmosphere, L.P.V. and H.P.V.}
\]

\[
m = \text{mass of gas}.
\]

\[
v = \text{velocity}.
\]

\[
S = \text{volumetric speed}.
\]

\[
W = \text{work}.
\]

\[
w = \text{power}.
\]

\[
\rho = \text{density}.
\]

\[
\eta = \text{viscosity}.
\]

\[
\varepsilon = \text{friction coefficient}.
\]

\[
E = E_{\text{mech.}} = \text{mechanical efficiency}.
\]

\[
E_{\text{vom.}} = \text{volumetric efficiency}.
\]

§ (3) WORKING CHARACTERISTICS.—Pumps may be distinguished either according to their working characteristics or according to the principles on which the action depends. Of the working characteristics the following are the most important of those applicable to pumps of all types:

Range of Pressure.—If any pump be worked continuously between closed vessels, there will ultimately be established in them constant pressures, \( p_a, p_t \). By the range of pressure is meant either (a) the ratio \( p_f^H/p_f \), or (b) the difference \( p_f^H - p_f \). (a) is generally the more important quantity and will here be termed the "range," denoted by \( \alpha "; for it is often approximately independent of the absolute values \( p_a, p_t \). But it is never completely independent; for all pumps have a minimum below which they will not reduce \( p_f \), whatever is the value, above this limit of \( p_f \) and all have a maximum \( p_t \) though it may be determined only by mechanical strength.

The range of a pump of any given type may be increased by working two or more similar pumps in series to form a "composite" pump, the L.P.V. of one being the H.P.V. of the next. In all important cases, the range of the composite pump is approximately or exactly the product of the ranges of the components. But a composite pump can also be built up of components of different types; no general statement can be made about the relation between the range of such a composite pump and those of its components.

§ (4) SPEED OF PUMPING.—The speed is the rate at which gas is transferred from the L.P.V. to the H.P.V. The amount of gas is usually estimated by its volume at the pressure of the L.P.V., whether the pump is a compressor or an evacuator. The speed so estimated is called the "volumetric speed," \( S \), and is expressed in volume \( m \) per unit time.

Measurements of \( S \) are usually observations of the change of \( p_t \) of a pressur or of \( p_a \) in an evacuator, \( S \) or L.P.V. being completely closed during the measurement is small.
with \( p_i \) or \( p_o \), the gas may be regarded as perfect. Consequently for an evacuator

\[
S = \frac{1}{\rho} \frac{dV}{dt} = \frac{1}{\rho} \frac{dp_i}{dt} = V \frac{d}{dt} \left( \log_e p_i \right).
\]

(1)

In a compressor, \( p_o \) is constant and equal to \( P \). Therefore

\[
S = V \frac{d}{dt} \left( \log_e p_o \right).
\]

(3)

In blowers the volume involved in \( S \) is usually estimated at \( p_i \). It is conveniently measured by some type of flow-meter placed in the outlet or inlet pipe. If the pressure at the point where the meter is placed differs considerably from \( p_i \), a correction must be applied to the readings of the meter. \( S \) is usually a function of \( p_i \) and \( p_o \) as well as of the nature of the pump; but there are important exceptions. The range \( s \) or the maximum difference of pressure \( p_{i0} - p_{i0} \) is given by a pair \( (p_n, p_o) \) such that \( S = 0 \).

§ 5 The Efficiency.—Several kinds of efficiencies are recognized as applicable to pumps and blowers; of these the mechanical efficiency, or the ratio of the useful work done to the total work expended, is alone applicable to all types. Both terms of the ratio need further definition to rid them of ambiguity. The work expended is usually taken to mean either \( a \) the work expended on the gas in giving to it energy, compressive, kinetic, or thermal, or \( b \) the work supplied to the mechanism of which the pump consists, including that lost in friction of solid or liquid parts. The efficiency reckoned with \( a \) is often termed the "gas" efficiency; that reckoned with \( b \) the "over-all" efficiency.

In pumps, where the L.P.V. and H.P.V.'s are separate, the useful work is always taken to be that required to transfer the gas that has actually passed from the former to the latter. This work will be least if the transference is effected reversibly: if the L.P.V. and H.P.V.'s are at the same temperature, the reversible transference must be isothermal, and any change of temperature during the process involves the expenditure of more work. If the transference is reversible and isothermal, the work required to transfer a mass of gas between the atmosphere at constant pressure \( P \) and a closed vessel, the pressure in which is changed by the transference from \( P \) to \( p_i \), is given by

\[
W = \int_{p_i}^{p_o} (1 - p_i) dV, \quad \ldots \quad (3)
\]

where \( V = (p) \) is the isothermal characteristic of the mass of the gas occupying the closed vessel at the pressure \( p_i \). If the gas is perfect, \( (3) \) applied to an evacuator or compressor becomes

\[
W = p_i V \frac{p_i - p_o}{\log_e \left( \frac{p_i}{p_o} \right)} \quad (4)
\]

\[
= p_i V \left( \log_e \frac{p_i}{p_o} - 1 \right) \quad (5)
\]

If \( P - p_i = \delta p \) is small, \( (5) \) becomes

\[
W = \frac{1}{2} \delta p V \quad (6)
\]

If \( p_i \) is small, as in a high evacuator, it becomes

\[
W = (1 - \frac{1}{P}) V \quad \ldots \quad (7)
\]

In some text-books, the work done by the atmosphere is left out of account; the term in \( H \) is omitted from \( (3) \), and the second and third terms in the bracket in \( (6) \). But since work is always done by or on the atmosphere in compressing or evacuating, the efficiencies reckoned without these terms would seem to have no practical significance.

In blowers the useful effect is usually estimated by the volume of gas produced at a given pressure. The work required to force a mass of gas from the atmosphere into a vessel in which the pressure is maintained constant and equal to \( p_i \) (by increasing the volume of the vessel as the gas enters) is given by

\[
W = (P - p_i) V \quad \ldots \quad (8)
\]

where \( V \) is the volume of the gas at pressure \( p_i \). Consequently, if \( S \) is the volumetric speed, and \( W \) the work done per second,

\[
w = (P - p_i) S \quad \ldots \quad (9)
\]

The stream of gas issuing from a blower possesses kinetic energy. If the work expended in giving to it this energy is to be included as useful work, there must be added within the bracket in \( (9) \) the term \( p_i = \frac{1}{2} \rho v^2 \). It is often impossible practically to convert this kinetic energy into energy of any other form without stopping the flow which is the main purpose of the blower; accordingly the total efficiency, as it is called, reckoned from the relation

\[
w = (P_e + p_i - 1) S \quad \ldots \quad (9a)
\]

in is often misleading. But it may be noted that ideally it is always possible to reduce \( P_e \) to zero without changing \( S \), and thus to "convert velocity into pressure"; for if the cross section of the stream is made infinitely large, an infinitely small \( v \) will give a finite \( S \).

In addition to the mechanical efficiency, there is recognised for many pumps a quantity known as the volumetric efficiency. But since this quantity cannot be defined generally for all types of pump, it will be discussed in connection with those to which it applies.
§ (6).—The remaining working characteristics common to all pumps are less capable of precise measurement; but they are none the less important. They include simplicity and convenience, first cost and cost of maintenance, adaptation to available sources of power, and so on. When several types of pump are permissible, it is usually these characteristics rather than any measurable efficiency which determine the choice. They will be noticed in connection with particular types.

§ (7) PRINCIPLES OF ACTION.—For the detailed consideration of the various types of pump, it is more convenient to adopt a classification based upon the principles underlying the action. Here pumps fall into three great classes:

A. Aerostatic.
B. Aerodynamic.
C. Molecular or High-vacuum.

In an aerostatic pump the transferance of gas is effected by forces that are at any instant in statical equilibrium. For any particular pump the range of pressure is independent of the speed of working within wide limits; the pump can be worked infinitely slowly without loss of range or of efficiency. (This statement is not strictly true if the viscosity of a lubricating liquid is used to secure gas-tightness, such pumps are dynamical, but not aerostatic.) In all practical examples the statical forces are those due to compression, but those due to change of temperature might conceivably be used.

In an aerodynamic pump the forces on the gas are dynamical, and vary with the motion of the parts of the pump; they cease when the speed of working becomes infinitely small, so that the range and speed of the pump vanish together. These dynamical forces arise from the inertia or viscosity of the gas.

The distinction between the two classes can be expressed less formally, but perhaps more clearly, by saying that in the first class, but not in the second, the action is "positive" in the engineering sense; or that, while it is impossible to blow through a pump of the first class, it is possible to blow through one of the second.

In both these classes the forces are such as are associated with a continuous medium. In the third class the action is due to "forces" apposite to the molecular but not on the molecular scale. The class would properly be termed "molecular" but since that term has been appropriated to a particular member of it, the less scientific expression "high-vacuum" pumps will be used.

In addition to these three classes of pump there are some methods of evacuation which scarcely justify the definition of pumping, but will be conveniently noticed briefly at the end of this article.

A. AEROSTATIC PUMPS

§ (8) BARTHEI AND SPRING.—The working part is always a vessel (V) of variable volume, v.

\[ (L \text{ or } H) \quad \left( p_0 \right)_{n+1} = \frac{(p_n)_{n+1} v_n + p_n v_{n+1}}{V_n} \]  

(10)

In a compressor or evacuator we have from (10)

\[ (L \text{ or } H) \quad \left( p_0 \right)_{n+1} = \left( \frac{v_n}{v_{n+1}} \right) \left( \frac{p_n}{p_{n+1}} \right)^{\frac{V_n}{V_{n+1}}} \]  

(11)

In a no-compressor or evacuator when we have from (10)

\[ (L \text{ or } H) \quad \left( p_0 \right)_{n+1} = \left( \frac{v_n}{v_{n+1}} \right) \left( \frac{p_n}{p_{n+1}} \right)^{\frac{V_n}{V_{n+1}}} \]  

(11)

In a no-compressor or evacuator when we have from (10)

\[ (L \text{ or } H) \quad \left( p_0 \right)_{n+1} = \left( \frac{v_n}{v_{n+1}} \right) \left( \frac{p_n}{p_{n+1}} \right)^{\frac{V_n}{V_{n+1}}} \]  

(11)

From (12) and (1) we obtain for the volumetric speed of an evacuator

\[ S = \frac{NV}{V_n + v_n (p_n - p_0 v_n)} \]  

(13)

and for that of a compressor

\[ S = \frac{NV}{V_n + v_n (p_n - p_0 v_n)} \]  

(14)

The range of pressure is given by \( S = 0 \).

Consequently

\[ (L \text{ or } H) \quad \frac{p_0}{V_n} = \frac{v_n}{v_n (p_n - p_0 \frac{V_n}{V_n})} \]  

(15)

The range, measured by the ratio of the pressures, is independent of the initial pressure and of the volumes of the L.P.V. and H.P.V.

These relations become very simple when \( v_n \), the volume of the "dead space," is zero. Then (11)-(14) become

\[ \frac{p_0}{V_n} = 1 + \frac{v_n}{V_n} \]  

(16)
\[ p_L = \left( \frac{V_L}{V_L + \Delta V_L} \right) (\text{evacuator}) \]  
\[ S = \frac{N_{v_L}}{(V_L + \Delta V_L)} (\text{compressor}) \]  
\[ S = \frac{N_{v_L} V_L}{(V_L + \Delta V_L)} (\text{evacuator}) \]  

Thus the volumetric speed of such a pump would be independent of the pressure against which it worked; its range would be infinite.

\[ \text{(9) VOLUMETRIC EFFICIENCY. — In an actual pump the ideal cycle performed: the yield is always less than that given by (10)-(14), and a fortiori less than that given by (10)-(19) on the assumption of no dead space. The deficiency is due to incomplete "connection" and "disconnection" of the L.P.V. and H.P.V. with U and with each other, i.e. to leakage and to a failure to establish pressure equiphant.} \]

The comparison of an actual with an ideal pump is made in terms of the "volumetric efficiency" \( (E_{v,\text{a}}) \), which may be roughly defined as the ratio of the number of cycles in which an ideal pump would produce a given effect to the number of cycles in which the actual pump produces the same effect. The ideal pump is assumed to have the same \( \Delta V_L \) (e.g. cylinder volume) as the actual pump; it is also assumed to have no dead space \( \Delta V_L \). This last assumption is not necessary, for the effect of the dead space can be readily calculated if the pump is otherwise ideal; but in the pumps for which the assumption of volumetric efficiency is most important, \( \Delta V_L \) is always made as small as possible, and its magnitude is important in judging the excellence of the design.

The "effect" by which \( E_{v,\text{a}} \) is estimated must be defined. It is usually either (1) the attainment of a given \( p_H/1 \) or \( p_H/1 \), or (2) the transformation of a given quantity of gas with a fixed \( p_H \) or \( p_H \). In case (1), \( E_{v,\text{a}} \) is a function of \( p_H \) or \( p_H \), and the value of this pressure must be stated. For a given \( p_H \) or \( p_H \), \( E_{v,\text{a}} \) will not in general be the same for (1) and for (2).

If (1) is adopted, and if \( N \) is the number of cycles in which the actual pump establishes the assigned \( p_H/1 \) or \( p_H/1 \), then from (10) and (17)

\[ E_{v,\text{a}} = \frac{\text{pm} - \text{pm}}{\text{m}_{\text{m}}/1} (\text{compressor}) \]  
\[ = \log \left( \frac{p_H/1}{p_H/1} \right) (\text{evacuator}) \]  
\[ E_{v,\text{a}} = \frac{S(V_L + \Delta V_L)}{N_{v_L} V_L} (\text{compressor}) \]  
\[ E_{v,\text{a}} = \frac{S(V_L + \Delta V_L)}{N_{v_L} V_L} (\text{evacuator}) \]  

If the H.P.V. or L.P.V. is not at atmospheric temperature, (20)-(23) must be corrected by the substitution of \( V_H/1, V_H/1, p_H/1 \) for \( V_H/1, p_H/1 \).  

\[ \text{(10) OTHER CHARACTERISTICS. — The advantage which aerostatic pumps possess over other types lies in the great range which can be obtained with them. They are, therefore, well suited for the production of very high or very low pressures in a single operation; but extreme pressures can be obtained with other types combined in composite pumps. They are in general less well suited for the transference of large volumes of gas under moderate differences of pressure, although some types (A., d) are used for this purpose.} \]

Their disadvantage is that they cannot exhaust vapours satisfactorily, especially when designed for a large range, for the vapours condense in U when its volume is reduced and do not pass readily into the H.P.V.; when the volume is increased again, they evacuate once more, return to the L.P.V., and keep \( p_H \) permanently at or above the vapour pressure of the substance. Permanent gas mixed with the vapour is removed very slowly after its partial pressure in the L.P.V. has fallen to that of the vapour.

The various types of aerostatic pumps are distinguished by the construction of U and the means adopted for connecting and disconnecting it with the L.P.V. and H.P.V.

The following sub-classes include conveniently all the important types:

Aa. Solid Piston Pumps.  
Ab. Liquid Piston Pumps.  
Ac. Flexible Container Pumps.  
Ad. Rotary Aerostatic Pumps.

Aa. Solid Piston Pumps

\[ \text{(11) The Von Guericke Pump. — This is the oldest type of gas-pump, and its invention is generally attributed to Otto von Guericke (1672); it was probably developed from the similar water-pump. It has still a wider sphere of use than any other type, being used for the attainment of pressures from 1000 atmos. to } 10^{-6} \text{ mm., and for volumetric speeds from many cubic feet to a few cubic millimetres per minute. It is equally familiar in heavy engineering, in delicate laboratory work, and, as the type pump, in everyday life. Broadly, the advantages of the type are a great range of pressure and great mechanical strength; the disadvantages, unreliability and mechanical inefficiency. It is unrivalled for high-pressure compressors, and for small portable laboratory evacuators; for all other purposes it can be replaced by other types. However, it is still widely used even for blowers, the purpose for which its disadvantages as compared with other types}} \]
AIR-PUMPS

are most marked. Its survival is probably due partly to its long history and to its resemblance to the reciprocating steam-engine, of which the constructional problems have been studied so completely.

The principle of the pump is familiar to all. The vessel U is a cylinder in which moves a piston. Connection is made to the L.P.V. and H.P.V. either (a) through ports in the cylinder wall opened and covered by the piston, or (b) through valves moved "positively" by the piston or the mechanism that actuates it, or (c) through valves opened and closed by the excess gas pressure. (c) is the oldest arrangement and the simplest to construct, but it represents a departure from the ideal cycle and necessarily reduces the range below the ideal limits; for the connection between U and the L.P.V. or H.P.V. ceases before the pressures have become equal. It is still standard practice in high-pressure compressors; in evaporators for moderate vacua (a) is often used; in those intended for the lowest possible pressures, one at least of the valves must be of type (b).

§ (13).—Three kinds of piston pump may be considered rather fully. The high-pressure compressor, shown diagrammatically in Fig. 1, is always composite. It would not be impossible to obtain a range of pressure of 200 and a final pressure of 200 atmos. by a simple pump, but there are several reasons why the multi-stage pump is preferable. Thus, it is possible to cool the gas between the stages by the "intercoolers." C. By spacing the cranks evenly round the crankshaft a more even torque and a balanced motion can be obtained. The construction of each pump can be adapted to the pressures between which it has to work; the thickness of the metal can be increased, as shown in the figure, as the pressure increases; special piston packings and forced lubrication can be used in the H.P. cylinders. Some makers prefer water to oil as a lubricant at high pressures, and at the highest pressures the substitution seems necessary because oil would burn explosively.

The volumetric efficiency of such a pump should not be less than 80 per cent; the gas efficiency also about 80 per cent; and the over-all efficiency about 60 per cent. The work done on the gas may be measured, for the determination of the gas efficiency, by indicator diagrams taken from the cylinders. These efficiencies are determined largely by the completeness of the cooling, which is one of the most important features of these pumps; they are also determined by leakage and by throttling at the valves.

§ (13).—Fig. 2 shows a large-scale two-stage evaporator, such as is used for the condensers of steam-engines and for working pneumatic tubes. The slide-valves are similar to those of a steam-engine, but to secure smooth working connection is made between the L.P.V. and H.P.V. when the piston is in the extreme position. The pistons are connected in tandem. If the pump is to be worked by a reciprocating steam-engine it would be possible to use the same piston rod for the driving piston, and thus to avoid rotary motions and bearings and to reduce moving parts to a minimum; but this arrangement is seldom adopted; pump and motor are usually separate.

The volumetric efficiency should be about 86 per cent when \( p_{L} = 20 \) cm. of mercury or more; about 80 per cent at \( p_{L} = 5 \) cm.; for lower values of \( p_{L} \), \( P_{L} \) will fall rapidly, and \( p_{H} \) will not be less than 1 cm. The over-all efficiency should be not less than 50 per cent at the higher pressures.

§ (14).—Fig. 3 shows part of a laboratory condenser in very general use. The pump is composite with two stages; the high-pressure member presents no special features and is not shown; it is connected to H. In the low-pressure member shown, the piston is covered with oil which is ejected at the end of the stroke through the valve V, carrying the air with it. At the same time the crank U, worked by the piston guide K, forces oil into the space O by means of the oil-pump R; from O the oil flows on to the top of the piston as it descends. It is claimed that the pump will attain \( 10^{-6} \) mm., if the gas and oil are free from vapour. A drying tube with \( P_{L} \) is necessary in the connection L to the L.P.V., and moisture, which can be filled with Cy, is desirable in the outlet of the H.P. cylinder to keep the oil dry. The pump is very
efficient and convenient down to pressures of 0.01 mm, but to obtain the highest vacua of which the pump is capable needs great care in its treatment.

A piston pump for extremely low pressures has also been developed by Gaede \(^1\) (1); in principle it does not differ greatly from that shown. In order to free the oil from water, and thus to dispense with a drying agent, the oil is forced through a special woven material which effects a separation of the two liquids. Gaede claims that his pump without any drying agent will attain a pressure of \(10^{-8}\) mm.

Abb. Liquid Piston Pumps

§ (15) Torricelli's Pump (2),(3).—It is impossible to make a perfect fit or a gas-tight joint between solid bodies movable relatively to each other; and therefore all truly solid piston pumps have some leakage and some dead space. Leakage can be wholly prevented and dead space very nearly abolished by using a liquid in place of a solid for the moving portion of the vessel \(U\). The ratio \(p_v/p_f\) can be increased by the substitution, and higher vacua (or higher compressions—though this result is not so important practically) obtained in a single operation. In fact a liquid is actually used in this manner in pumps which are usually regarded as of the solid piston type. In the pump described last, the oil covering the "piston" and passing through the valves is really the piston, and the same purpose is served, in part at least, by the lubricating liquid of other pumps of section An. However, the typical liquid piston pumps were developed historically from Torricelli's, and not Guericke's, method of evacuation; and the distinction between solid and liquid pistons, though slight from the standpoint of scientific principle, is perfectly clear in all practical examples.

In the Torricellian pump the vessel to be evacuated is completely filled with a liquid of density \(\rho\); the open end is placed beneath the free surface of a liquid, which is usually the same as that filling the vessel. If, in this position, any part of the vessel is at a height above the free liquid surface greater than \(h\), where \(h=\frac{1}{\rho_g}(11-P)\), the surface of the liquid will sink to the height \(h\), and the upper part of the vessel will contain only the vapour of the liquid at the pressure \(P\) corresponding to the prevailing temperature. As a liquid for such a pump, mercury is especially suitable, both on account of its high density and small "barometric height," \(h\), and on account of its low vapour pressure.

This method of evacuation has the obvious disadvantage that the whole L.D.V. has to be filled with liquid and inverted. A very obvious modification of it was described in principle by Swedenborg (1722) and put into a practical form by Grazioli (1828). The action is clear from Fig. 4; the mercury is alternately raised and lowered and the two-way cock alternately connected to the air and to the vessel to be evacuated. The pump is a true liquid piston pump, differing from Guericke's pump only in the nature of the piston and the valves.

§ (16) The Newman Pump. — A greatly improved form of the pump originally due to Tippler (4), but realised practically by Hayes and Nesson (5), is shown in Fig. 5; no stop-cocks are required. It was used in many classical researches on low vacua at the end of the nineteenth century, being at that time rivalled only by the Sprengel pump (see below) as a means of attaining low pressures.

By raising the reservoir \(A\) mercury is driven up into the cylinder \(B\), thereby driving out the gas from the cylinder through the capillary tube \(C\), from which it may be collected in the mercury trough. Mercury is prevented from flowing over into the vessel.
to be exhausted (V) by the small glass valve D.

On lowering the reservoir, the mercury flows back from the cylinder, and when the mercury reaches the lower part of the cylinder gas will enter from the vessel V through the side-tube E ready for expulsion at the next stroke.

The lowering of the reservoir must be done very slowly so long as the pressure in V is more than 2-3 mm, otherwise air entering the cylinder through the side-tube E will carry mercury violently up the tube F, and this may easily shatter the glass-work of the cylinder.

When the vacuum becomes high, the raising of the reservoir must be done very slowly, otherwise the "hammer" of the mercury at the top of its travel in the cylinder will break the cylinder head.

The reservoir A should have about twice the capacity of B. The volume of the cylinder B is fixed by the work required from the pump, and in ordinary laboratory models is from 500 to 600 c.c. The capillary tube C is about 800 mm long and 1 mm bore. The tube F should have a bore 12 mm, and the tube E about 4 mm. This ensures that gas entering from E to F will tend to travel in bubbles upward through the mercury in F, instead of carrying the mercury solidly up with it.

The P₂O₅ tube is, of course, inserted to absorb water-vapour, which prevents the same obstacle to this as to all aerostatic pumps.

The lowest pressure which it is possible to obtain with this pump is determined as in (15) by the ratio \( \frac{\rho V}{\rho_b} \), \( \rho \) is the volume of B, while \( \rho_b \) is the volume of the smallest bubble which the mercury will carry down the capillary C. This volume is approximately that enclosed between the convex surfaces of two mercury maniscues which just touch; it decreases with the bore of the capillary. But there is some gas adhering to the glass in addition to actual bubbles left behind by the mercury, which makes it useless to decrease that bore below a certain limit. The lowest pressure recorded as attained by a Töpler pump is 0.000025 mm— in addition, of course, to the vapour pressure of the mercury.

The working of a Töpler by hand is extremely tedious, for several hours may be required to reach the limit of pressure. Numberless devices for rendering its action automatic have been proposed; electrical contacts worked by the mercury, or else the weight of the mercury, are used to control the operation. But no description of them is necessary today, for the problem of the automatic Töpler seems to have been solved finally by Ghele (9), who proposed to move the solid vessel rather than the liquid piston.

§ (17) GÁRDE ROTARY MERCURY PUMP.—

The general action of the pump can be seen from Figs. 6, 7, which are vertical sections parallel and at right angles to the front of the pumps. The outer casing A contains mercury to about two-thirds of its height, and is connected through the pipe B with a rough vacuum pump (e.g. an ordinary piston pump) capable of maintaining a pressure of about 10 mm. An ingenious device shown in Fig. 8 is used for cutting off the rough pump after the preliminary exhaustion. Inside this casing rotates a drum B, made of porcelain, to the side of which is attached a smaller porcelain drum C. The two drums communicate through the port D.

It will be seen from this diagram that if B is rotated in the direction of the arrow, the portion of B above the mercury will communicate with the pipe V, connected to the vessel to be exhausted, so long as the port D is not immersed. As soon as D is immersed, the communication with V is closed, and when the tail end E of the drum rises above the mercury, the gas will be passed on to the rough vacuum.

In the pump as actually manufactured two or three drums are spaced symmetrically on the same axle; a second drum is indicated by the dotted line in Fig. 6. The speed of the pump is thereby increased, but the construction made much more complicated.

The range of the Gárdé pump is probably somewhat less than that of the Töpler, for the conditions for the expulsion of small bubbles from U are less favourable. But since \( \rho_b \) is less, owing to the use of the auxiliary pump and since its speed is much greater, the least pressure practically attainable is at least as low; a pressure of 0.00005 mm is well within its power. The volumetric speed is not constant, as it would be according to (10); it is about 110 cm³/sec at 0.01 mm, and falls off continuously at the lowest pressures.

§ (18) THE SPRINGER PUMP.—A liquid piston pump, using mercury but working on
a somewhat different principle from those just described, was invented by Sprengel in 1805 (7). It has over the Geisler (and later Tüpler) pump the greater advantage that its action is more nearly continuous and automatic. The gas is carried out of the L.P.V. by the fall of mercury down a capillary tube, as in the Tüpler pump; but it is not forced into that tube; it enters the tube under the pressure in the L.P.V. and is there trapped between successive drops of mercury falling into the top of the tube from a reservoir. In another and more convenient arrangement (Fig. 9) the drops are formed in the capillary by the entrance of gas from the L.P.V. through a side tube. But the principle is the same; the liquid column in the capillary will break up into drops, trapping the gas between them, if the gain in surface tension energy due to the formation of a liquid-gas surface is greater than the loss in hydrosstatic energy due to the accompanying displacement of the liquid. The precise calculation of the conditions for drop formation is complicated; but it is clear that the bore of the capillary must be below the limit at which drops could be formed in the tube without completely occupying its cross-section.

The volumetric speed of a "single-fall" Sprengel is extremely small, not more than a few cubic millimetres per second. It can be increased by connecting in parallel several capillary tubes all fed from the same reservoir, and thus making a "multiple-fall" pump. The greatest pressure attainable is fixed by the same considerations as in the Tüpler pump, but it may be increased by small quantities of air carried into the vacuum by the stream of mercury from the reservoir exposed to the atmosphere. Many devices have been suggested for avoiding this defect. (See (3)).

The Sprengel pump can be made completely automatic, if it is arranged that the mercury which has fallen down the capillary is restored periodically to the reservoir. Such an automatic form was at one time in universal use for the exhaustion of electric lamps (8). It is shown in Fig. 10, and the method of operation is obvious from that figure.

The outlet is connected to an auxiliary pump maintaining a pressure of a few cm. The capillary tube A, into which mercury flows from D through the jets C, are therefore relatively short (about 20 cm.). The bent tube B enables the end of the exhaustion to be seen by the disappearance of gas-bubbles from the mercury.

The reservoir E is normally connected to H; an occasional admission of air, in order to restore the mercury to D, is controlled by a simple timing device set once and for all. It can also be controlled by the weight of the mercury in the reservoir.

The common laboratory mercury still is in effect a Sprengel pump whereby gases introduced by the mercury are removed.

For high-vacuum work, mercury pumps of these types, with the possible exception of the Geisler pump, are obsolete, and replaced by devices of Class C. They may, however, be used as auxiliary pumps in series with those of that class when it is desired to collect gases pumped out from a vessel. For this purpose the Tüpler A- pump is most suitable.

§ (10) Chemical and Other Pumps.

The foregoing pumps are designed to attain low pressures. But liquid piston pumps are also of service for pumping chemically active gases, which would attack any of the metals or other materials suitable for the construction of solid piston pumps. Thus for the compression of chlorine, pumps are used of which the cylinder and valves are made of lead-covered steel, while the piston consists of oil or sulphuric acid. The liquid piston is set in motion either by compressed air or by a solid piston working in one limb of a U-tube, the other limb of which is the chlorine pump.

Laboratory pumps essentially similar to the Tüpler, but using oil or glycerine or sulphuric acid in place of mercury, have also been used for some purposes. The lower densities of these liquids enable the pumps to be made of glass with a volume much greater than that set by the mechanical strength of the glass if mercury were used; or the gas to be pumped may be one which attacks mercury.

Again, air compressors for high pressures have been constructed in which water is used as the piston in order that the cooling of the gas may be more efficient. In some of these metal chains hanging into the water from the top of the piston have been used to facilitate the transfer of heat between the gas and the liquid.

Ac. Flexible Containers

§ (20) Bellows. — In these pumps the vessel U has flexible walls and its volume is varied by
AIR-PUMPS

The board B falls by its own weight and the air enters through the flat valve V. Air is compressed in the former by a hand lever, and the air is driven through the valves V₂ into the reservoir bellows D, from which the air passes to the organ. The pressure on D depends on the weight W on the top board. To ensure a uniform pressure in D whether it is expanded or contracted a double set of ribs is used, the upper set R₁ folding outwards and lower set R₂ folding inwards; the frame 11 between the two sets of ribs is connected by a mechanism shown so that both halves of the reservoir bellows expand equally.

§ (22).—At the opposite extremity of the type is the squeezer rubber tube pump (Fig. 13) (10).

This pump consists of a rubber tube A₁A₂ (Fig. 5) wrapped inside a hollow cylinder B and squeezed by two or more rollers C₁ and C₂ so that the way through the tube is stopped at the squeezer portion. The rollers C₁ and C₂ roll round the inside of the cylinder driven by the shaft D, and gas (or liquid) is transferred from A₁ to A₂ as the shaft revolves. The squeezer portions act as pistons, and these “pistons” are formed at A₁ and travel along the tube to A₂ where they disappear.

The action of the pump is somewhat similar to the rotary pump of Fig. 10, with the important difference that the “pistons” of the rotary pump requires to be carried across from A₂ to A₁, and is thus liable to cause leakage of air or liquid. The tube pump has no dead-space and is only limited in range by the strength and tightness of the rubber tube to resist the pressure difference; but its speed is small and mechanically it is inefficient. The tube pump is particularly suitable for transferring gases or liquids without contamination, as the plain tube can be easily cleaned and no other portion of the pump can come into contact with the fluid being pumped.

An even simpler pump of the same type can clearly be made out of a plain piece of rubber tubing pressed with the fingers.

Ad. Rotary Pumps

§ (23) BLOWERS.—In this class the variation of the volume of U is effected by the rotary motion of solid bodies constituting part of its walls. The pumps are usually driven by...
AIR-PUMPS

... are intended for continuous action; note therefore with solid piston pumps or with other types of Class A. Over on pumps they have the advantages... and consequently in cost, both and for upkeep; in compactness; the... air current when used as...

They have disadvantage in a smaller... pressure, in greater leakage, and in noiseless. But pumps of this type also with those of Class B

y B). For blowers type B has the advantage in mechanical and simplicity. For compressors little to choose between B and though the latter has the greater th types would be replaced by Aa
cor range were required. For evacua

is useless, while Ad provides the machines of modern practice for all between 10 mm. and -011 mm.

brief examples of the class can be into two groups, one (1) developed from the Root Blower, the other (2) from the Beale Blower. The development has been so gradual that it is difficult to associate any of the pumps, or even the two archetypes, with the name of any inventor. The groups are usually distinct by the nature of the "abutment," that line or surface dividing the H.P.V. o L.P.V.; group (1) is then characterized by a movable abutment, (2) by a fixed abutment; for though in (2) the bodies the abutment move, the line or surfa is the abutment is at rest relatively housing.

MOVABLE ABUTMENT.—These pumps were used for moving large quantities against a small pressure difference to 5-10 feet water pressure). A very early example of this type was exhibited (Exhibition by Elsin Root in 14). It consists of two two-toothed A, B, which are made to revolve at a rate in opposite directions by means outside the box or pump body; the movement between the wheels and the in U, and its volume varies with the of the wheels. If they rotate as in the figure air would be sucked in at delivered through D.

several leakage the wings are machined accurately an possible, and are often with wood or other packing material. (Incompressible efficiency against small pressure 10 inches of water) may be 80 per cent, while at higher pressure (of water) it will drop to 80 per cent. The over-all mechanical efficiency is about 75 per cent.

Fig. 15 shows another type where the impeller vanes V are fastened at one end to a disc which causes them to rotate around the fixed core. The vanes after the delivery stroke come into the openings in the rotating body A (called the stator), which is caused to rotate at the same speed as the vanes by gears on the outside. On rotat

further the vanes come into the suction chamber, whence they start again on the compression stroke.

The pump is more complicated than the Root, but several advantages are claimed. Thus surfaces can be used to separate the two chambers where lines only are possible in the Root blower; air is compressed by one rotating part only; there is no contact between parts moving with different velocity, and thus there is less friction; the mechanical construction is simple and cheap; the pulsations of gas are reduced.

In another type the rotating parts are spiral vanes, which give a more even delivery of gas and make less noise; the mechanism is not easily shown in a diagram. Many other devices have been adopted, some varying widely in detail from those mentioned, but all based on the same principle; descriptions of them are to be found in makers' catalogues.

§ 25 FIXED ABUTMENT.—These pumps, of which the Beale blower is an early example, are used extensively as compressors, as blowers, and as evacuators. They are used in gasworks for pumping the gas to the holders, and in the factory or laboratory for attaining pressures down to 001 mm.

The general principle employed is shown in Fig. 16.

The cylinder D rotates about an axis O, so that it touches the containing cylinder C at the fixed abutment B. A slot in D carries the blades or "scrapers," the outer ends of which are held against the containing cylinder C. The blades divide the space between C and D into two parts; as D rotates the volumes of these two parts vary in a manner readily seen from the figure, in which D is the suction and Q the compression inlet.

The friction of the scrapers on the cylinder involves considerable loss and wear, and many alternative arrangements have been devised
to avoid it. In one, contact between the scrapers and the cylinder is preserved by a circular guide with its center coincident with that of C. In another there is a single solid scraper which slides freely in the slot in D; the section of the cylinder D is not circular, but such that the two ends of the scraper are in contact with the walls whatever the position of D. In another the scrapers are pressed out by springs, but they bear on an idly rotating cylinder C' fitting closely within C and pierced with holes; the clearance between C and C' is made so small that the leakage between the two is inappreciable; the friction is then reduced to that of C' on its bearings. In any pump of this type, the number of scrapers may be increased. Fig. 17 shows a type with three or more scrapers, hinged at the central axis M of the cylinder B, and sliding in cylindrical stuffing boxes C fastened to the rotating drum D; this drum touches the casing in the fixed abutment E.

In pumps of this type designed as evacuators oil is always introduced into the cylinder to prevent leakage and oil in the dead space. The scrapers are usually arranged as in Fig. 16. In order to prevent hammering by the oil when the vacuum is high, a valve is fitted which limits the quantity of oil flowing from the compression side; it also helps to separate the air from the oil. Such evacuators are often run in tandem, or one of them is used in series with an auxiliary pump of some other kind. If \( p_{bn} \) is 4 to 10 mm., \( p_b \) may be reduced to -0001 mm.

Scrapers evacuators are largely used as auxiliaries to high-vacuum pumps (C); they are also the chief type employed in the preliminary evacuation of electric incandescent lamps, which are subsequently "cleaned-up" by the discharge (D).  

B. AERODYNAMIC PUMPS  

§ (26).—In aerodynamical pumps, the pressures are functions of \( S \) and of the velocity of the gas in different parts of the apparatus. The fundamental connection between the pressure and velocity of any fluid is given by the familiar hydrodynamical equation

\[
\frac{d(p + \rho v^2)}{dS} = 0 \quad \text{or} \quad p_1 - p_2 = \rho(v_1^2 - v_2^2) \]

It is deduced on the assumptions (1) that the energy required to change the pressure of a volume \( V \) of the gas from \( p_1 \) to \( p_2 \) is \( (p_1 - p_2)V \), (2) that the energy of any such change of pressure which occurs is equal to the change in the kinetic energy of the gas. (1) implies that the fluid is incompressible, or that the change in pressure is infinitely small; (2) that there is no loss or gain of energy to or from other sources, e.g., friction of the moving gas. By "the pressure" must be understood the force per unit area on a surface at rest relative to the gas; in a frictionless fluid it is equal at any point to the "static" pressure on a surface parallel to the flow at that point, but moving relatively to the gas; the "dynamic" pressure, or that on a surface perpendicular to the flow and at rest relative to the pump, is \( p + \rho v^2 \), and, when (24) is true, is constant along the whole stream.

Bc. Injectors and Ejectors—Gaseous Stream  

(General Reference (11))

§ (27).—These are wholly analogous to liquid jet pumps (see "Hydraulics"). A gas or vapour (called "the fluid" to distinguish it from the gas to be pumped) is forced through a tube \( N \) from a reservoir \( R \), at pressure \( p_R \); into a larger tube \( O \) communicating with the atmosphere (see Fig. 18). If the flow satisfies the assumption (2) above, the stream would not be brought to rest in the atmosphere unless \( p_R \) were equal to \( H \), and if \( p_R = H \) there would be no stream. But owing to viscosity and friction, \( p_R \) may be greater than \( H \), so that a high velocity \( v_R \) is obtained in \( N \), and yet \( v \) may be zero when the atmosphere is touched. In these conditions, the difference \( H - p \), where \( p \) is the pressure at \( N \), is not so great as \( \rho v_R^2 \) given by (24); but it is still finite and of the same sign; \( p \) is less than \( H \).

If gas in the space surrounding \( N \) is given access to the stream through the gap between \( N \) and \( O \), it will flow into the stream of fluid and be carried away by the stream, so long as its pressure is greater than \( p \). The fluid stream from \( N \) to \( O \) will suck gas through the pipe \( Q \) and will act as an evacuator or "ejector." In an "injector" or compressor, \( Q \) communicates with the atmosphere, and the space with which \( O \) communicates, and in which the stream comes to rest, is at a pressure greater than \( H \), but, of course, still much less than \( p_R \). \( p \) is equal to \( p_R \) in an ejector and to \( p^* \) in a compressor; but if there is a

1 Confusion is sometimes introduced by a failure to observe that the chief part of the pressure of a gas is incompressible from its compressibility: it is not due, like that of a liquid, to heat. This pressure of an incompressible gas is a meaningless concept. The application of the theory to gases is justified only because, for small changes of pressure at constant temperature, \( \frac{dV}{V} = - \frac{dp}{p} \).
continual stream of gas through the pump, $p_1$ or $p_0$ will not be equal to $p$, (1) because of the drop due to flow of the connecting tubes $Q$ and $O$, (2) because the mixing of the gas with the fluid affects greatly the velocity and pressure of the latter.

In calculating the performance of a pump, allowance has to be made for departures from (25) owing to friction and viscosity. The allowance is usually made by introducing on the right hand of (25) an empirical factor $\xi$, less than 1, and writing

$$p_1 - p_2 = \frac{1}{\mu} C_\xi (\frac{v_2}{v_0})^2 - \eta J,$$  
(26)

where $v_1$, $v_2$ are the mean velocities over a cross-section of the stream. The principle of the calculation is then simple. There are three equations (26) for the three tubes $N$, $O$, $Q$; and there is the equation of conservation of mass when the streams meet. (The moment is not conserved, for there is a reaction on the tubes.) These four equations suffice to determine the four unknowns, viz. $p$, $v_1$, $v_0$, $\eta$ in terms of $p_1$, $p_0$, $p_0^2$, the densities $\rho_1$ and $\rho_0$ of the gas and fluid, the three empirical constants for the three tubes, $F_1$, $F_2$, $F_0$, $F_0^2$, $F_0$, $f_0$, $f_1$, $f_2$, the cross-sections of the two tubes at their openings. The algebra need not be set out, for the numerical results depend wholly on the values attributed to the empirical constants; it is given in (11). Here it will suffice to state some of the most important qualitative conclusions, which are confirmed by experiment. These were first stated by Zener (12).

The variables considered are $p_1$, $p_2$, $p_0$, $p_0^2$, $F_1$, $F_2$, $F_0$, $F_0^2$, $f_0$, $f_1$, $f_2$, $S$, the volumetric speed, which is equal to $v_0 F_0$. In each statement the variables not mentioned are supposed constant.

(1) $p_1 - p_2$ is proportional to $p_0^2$ and $v_0^2$, so long as $p_0$ is great compared with $p_1$ or $p_2$.

(2) $S$ is proportional to $\sqrt{\rho_1}$, to $v_0$, and to $p_1 - p_2$, subject to the same condition.

(3) $p_1 - p_2$ depends only on the ratios of the $F$'s, and not on their absolute values.

(4) $S$ is proportional to the $F$'s, if their ratios are constant.

(5) Given one of these ratios, there is an optimum value for the other two, giving maximum $S$, but the same maximum $S$ can be obtained with different values of the ratios.

(6) $S$ is independent of $\rho_1$ and $\rho_0$, so long as $v_0$ is constant.

(7) $S$ may be considerably greater than the volume of fluid passing per second from $N$, e.g. two or three times as great.

Owing to the circumstances in which the pumps are used, the efficiency is seldom important. But the mechanical efficiency reckoned on the basis of the work done in driving the fluid stream appears seldom, if ever, to exceed 25 per cent.

§ (28).—In practice the fluid used is generally steam or compressed air. Ejectors using these fluids are used for vacuum brakes, vacuum cleaners, and grain conveyors. Their great advantage is, of course, their simplicity and freedom from maintenance charges. Fig. 18 shows a pump used for railway vacuum brake operation. It will reduce $p_1$ to about 15 cm. of mercury. A more elaborate pump is shown diagrammatically in Fig. 19. Here a common supply of steam works two pumps in series. The first consists of the plain nozzle $A$, the second in the annular gap $B$, from which the gas is carried into the surrounding annular space $C$. It is claimed that this pump will attain a pressure of 3 cm. of mercury. Remark should be made that the application of the simple theory to such pumps is extremely precarious, for the assumption that the change of pressure of the gas is infinitesimal is clearly false.

Fig. 20 shows a blower used for moving large quantities of air in ventilation under a pressure of a few inches of water. Air or steam is used as fluid; the conical cones are designed to make the velocity of the gas nearly parallel to that of the fluid, so that the direction of flow of the latter is not disturbed by irregularities in the flow of the former. A somewhat similar arrangement is adopted in the smoke-box of a locomotive, where the exhaust steam is made to create a draught through the boiler flues.

§ (29).—The most modern development of this type is the mercury vapour jet pump used in conjunction with "condensation" high-vacuum pumps ($p_1$). Indeed, as will be seen, the line between vapour jet pumps and condensation pumps cannot be drawn sharply; roughly it may be set at the pressure where the mean free path of the vapour molecules becomes comparable with the dimension of the
AIR-PUMPS

but there is no justification for overlooking the distinction entirely. The construction of these vapour jet pumps is essentially similar to Fig. 18, but the apparatus is made of glass; the vapour stream is produced by boiling mercury, and condensing arrangements are provided for returning the vapour to the boiler. A practical form designed by Volmer (13) will reduce the pressure from \( p_2 = 20 \text{ mm.} \) of mercury to \( p_1 = 0.001 \text{ mm.} \) But it is doubtful whether they will replace generally the rotary aerostatic oil-pump for producing the auxiliary vacuum of high-vacuum pumps. Fugacity is their great fault.

By. Injectors and Ejectors—Liquid Streams

§ (30).—This type of pump, of which the laboratory filter pump (Fig. 21a) is a common example, is often regarded as a mere modification of its gas or vapour being replaced by a liquid as fluid. But the difference is really greater. If the theory of its is applied to pumps with liquid as fluid, then, even if all plausible corrections are made, the calculated performance is far less (e.g. 10 times) than the actual. The error arises in assuming that the gas and liquid are miscible. The flow of the gas into the fluid is not determined simply by the pressure difference, and relative motion of the fluid and gas is possible, even after they are mixed in the exit tube 0.

It seems preferable to look at their action from a different point of view. Two processes are involved: first, the entanglement of the gas by the liquid stream; second, the conveyance of the entangled gas from the L.P.V. to the H.P.V. During the second process the gas will move relatively to the liquid nearly as if the liquid were at rest relative to the walls. The difference of pressure ultimately obtainable is limited only by the condition that the velocity of the liquid entering the L.P.V. by \( N \) is sufficient to carry it out through 0 against the pressure \( p_1 - p_2 \) and is also greater than the velocity with which the bubbles of entangled gas travel through the liquid in the opposite direction. It is the second process which determines the greatest possible value of \( p_1 - p_2 \).

On the other hand, the speed of the pump is determined by the first process. Its nature is obscure; probably the liquid stream carries along a layer of gas on its surface, in virtue of friction and viscosity (cf. § (30)), as would a swift rod travelling with the same velocity. When the liquid breaks into drops in virtue of the inherent instability of liquid jets, this gas becomes entangled between the drops. On this view the performance of a pump of this type appears quite inadvisable. No calculations confirmed by experiment seem to have been based on any view, and few data of performance or of its variation with the construction of the pump seem available.

§ (31).—The filter pump of Fig. 21a fed with water at a head of 50 ft. or more will yield \( p_1 \) to the vapour pressure of the water. But no measurements of \( B \) under varying conditions have been found. It is recorded that the pump is more efficient if placed at the top of a building so high that the exit tube can be made as long as the water barometer.

A variant on the usual design is shown in Fig. 21b, which is similar in construction to the Venturi meter. But since the action is improved by a bulge at \( b \) which breaks up the stream, it is probable that, as suggested, the formation of drops is an important part of the process. A non-return valve, as shown at \( V \), is useful with both of these types to prevent the flow of water into the apparatus if the head becomes insufficient.

Evacuators of these types are applied outside the laboratory to vacuum cleaning and to grain conveyors. Compressors working on the same principle, but with a different construction, have also important commercial uses; they are known as “trumpets.” In a very simple form (Fig. 22), used for blowing blacksmith’s fires, a stream of water flowing down a pipe with a few holes in it drops with it air from the atmosphere, which is subsequently separated from the water in a closed vessel. A more elaborate form has been developed in America for supplying compressed air to mines where a great head of water is available. The pressure obtainable is a considerable fraction of that corresponding to the head of the water.

By. Centrifugal Pumps

(General Reference (11) and (14))

§ (32).—Centrifugal air-pumps are analogous to centrifugal liquid pumps (see “Hydraulics”). They are generally called “fans,” and are used as fans or blowers according to the definition of the introduction. The principle is shown in Fig. 23, which illustrates the simplest type. The gas entering the circular central aperture \( O \) in the housing is whirled round by the rotating vanes, acquires velocity, and issues through \( B \). Suppose that the conditions necessary for (24) are fulfilled, and that the gas leaves \( I \).
tips of the vanes with a radial velocity $v_r$, uniform over the whole surface of the circular cylinder surrounding the vanes. The area of this surface is $2\pi rl^2$, where $r$ is the radius of the vanes and $d$ their breadth perpendicular to the diagram. Then

$$S = F_1 r_1.$$  

If $F_1$ is the area of the opening, and $v_2$ is the velocity of exit uniform over the opening,

$$S = F_2 v_2.$$  

If the gas in acquiring its velocity from the vanes preserves its original pressure $p_1$, then from (24)

$$p_1 - p_0 = \frac{1}{2} \rho (v_1^2 - v_2^2) = \frac{1}{2} S^2 \left( \frac{1}{F_1^2} - \frac{1}{F_2^2} \right).$$  

But, as in Section 6e, (24) is not true and allowance has to be made for losses of energy due to friction and to sudden changes in the direction of the gas stream. Further, the velocities are not uniform over the surfaces $F_1$ and $F_2$. Again, it is convenient to express $p_1 - p_0$ and $S$ in terms of the velocity of the vanes which can be measured directly; it is usual to represent this velocity by $v_p$ the linear velocity of the tips. It may be assumed that $v_1$ and $v_2$ are proportional to $v_p$. The losses may be then represented by one or more terms proportional to $v_p^2$, or to $S^2$ or to $S v_p$, and the general equation for the performance of the pump written

$$p_1 - p_0 = \alpha v_p^2 + \beta v_p S + \gamma S^2.$$  

The constants $\alpha, \beta, \gamma$ are usually regarded as depending on the angles at which the stream of gas strikes the vanes and the housing; they certainly depend on the geometrical quantities characteristic of the pump. Some progress towards calculating them directly from those magnitudes can be made, but some purely empirical constants are always necessary. In designing the forms of the vanes and of the housing such calculations are a useful guide; here reference can only be made to discussions in (11) and (14). It may be noted that in (30), $\alpha$ is always positive, while $\beta$ is negative.

Three kinds of efficiency are recognised for centrifugal pumps:

§ (33).—The inmanometric efficiency $E_{\text{man}}$, is taken as $(p_1 - p_0)\rho v_p^2$, $p_1$ (usually 11) and $p_0$ being the static pressures of the inflowing and outflowing gas. If $v_1$ were equal to $v_p$, the maximum value of $E_{\text{man}}$ would be $\frac{1}{2}$, but since $v_1$ may be either greater or less than $v_p$, $E_{\text{man}}$ might theoretically have any value; actually it is seldom if ever greater than 1.

(\(i\)) The mechanical efficiency $E_{\text{mech}}$. The useful work is generally taken to be given by

$$(9),$$

so that if $w$ is the power exerted at the pump shaft, $E_{\text{work}} = \frac{S(p_1 - p_0)w}{m}$. Sometimes the useful work is reckoned by (9); the corresponding efficiency is called the total efficiency, but it is seldom important, as previously explained. $E_{\text{work}}$ is a true efficiency and can never be greater than 1.

(\(ii\)) The volumetric efficiency $E_{\text{vol}}$, which is taken by some writers to be $S/v_p^2$ and by others to be $8/2\pi r_1^2$. The latter quantity would be unity if $v_1$ were equal to $v_p$; the former seems to have no general significance, but, being a non-dimensional magnitude, is convenient for comparing similar designs. $E_{\text{vol}}$ is often greater than 1 if the first expression is chosen, sometimes if the latter is chosen.

It is apparent from (30) that the pressure and the efficiencies will vary with $S$, if $S$ is controlled by changes in the area $F_2$ or by other changes in the resistance to the flow of the gas. Fig. 24 shows typical curves relating the brake H.P. $w$, the pressure difference $p_1 - p_0$, and the mechanical efficiency to the volumetric speed $S$, the velocity of the vanes being constant. It will be observed that this efficiency is zero for $S = 0$ and for high values of $S$ has a maximum for some intermediate value. If mechanical efficiency is required the pump must be designed for its special work. If the velocity of the pump is varied over a moderate range, $S$ varies as $v_p^2$, and the power expanded is $v_p^2$. For extreme varieties the "constants" of (30) change.

§ (34).—Simple centrifugal fans differ in size, in the number and shape of the vanes, and in the shape of the housing surrounding them. This is often divided into a "diffuser," or portion with parallel sides immediately outside the vanes and a "volute," or portion of circular section, outside the diffuser. The cross-section of the volute increases towards the outlet in order to make some use of the kinetic energy (see § (6)). Some fans have inlet openings on both sides of the fan, some only on one. But in their performance, they all have common characteristics; they are all used as low-pressure blowers, the maximum pressure obtained being about 12 in.
of water; $p_n/p_a$ does not exceed 1.03, and assumption (1) of $\S$ (28) is justified. In large sizes their mechanical efficiency may reach 80 per cent, but usually it is more nearly 70 per cent and intermediate between that of piston pumps and of Roots' Blowers. Either of these types they have the advantage of simplicity and of being proof against hot and dusty gases if the bearings are suitably protected.

Composite, or multi-stage, centrifugal fans are also common. The fans of successive stages run on the same shaft; the discharge from the circumference of one fan is led by a tube to the central intake of the next. Since $p_n - p_a$ is proportional to $\rho$ by (25) and $\rho$ is proportional to $p_n$ or $p_m$ we have in successive stages $p_n - p_m = \varepsilon \rho$, or $p_n/p_m = \varepsilon$, where $\varepsilon$ is the range of the simple pump and $n$ is the number of stages. The range of the composite pump is the product of the ratio-ranges of the individual stages. Such multi-stage fans with ten or more stages, each giving $\varepsilon = 1.1$ when driven by a turbine or electric motor at 4000 r.p.m., are used to deliver air to blast furnaces at a pressure of 30 atmos. They are also used for "supercharging" petrol motors on aeroplanes.

3-stage fan of this kind is shown; details of bearings, rings to prevent leakage, and the water-jacket of the outer casing have been omitted. A, B, C are the revolving "impellers," while the parts drawn solid are fixed.

Roots constructed a simple fan, running at 20,000 r.p.m., which gave $\varepsilon = 1.5$; experiments on extremely high speeds have also been made by Parsons and others. But such simple fans seem to have no practical advantage over the composite type.

Dh. Airscrews

(General References (11) and (14))

$\S$ (35).—In type Bg, the velocity of the gas produced by a rotating solid is perpendicular to the axis of rotation; if the velocity is mainly parallel to that axis, the fan may be called a "propeller," or, better, airscrew. In all that concerns the general relations between the velocity of the solid and the velocity or pressure of the gas, airscrews are indistinguishable from centrifugal pumps. Thus the pressure produced by an airscrew is proportional to the square of its velocity, the volumetric speed to the velocity, and the power to the cube of the velocity. (35) is still true, at least approximately, and similarly defined efficiencies might be employed to state the performance.

The difference between airscrews and centrifugals lies in the connection between the constants of those equations and the geometrical magnitudes. Much more is known of this connection for airscrews, perhaps on account of their importance for other purposes; for this knowledge reference may be made to "Aerodynamics"; since airscrew pumps are not very important, no further account of their theory need be given here.

$\S$ (36).—Airscrews are largely used for ventilation, either stirring up the air in a room or extracting it into the atmosphere through a hole in the wall. A plain airscrew is very inefficient for the second purpose, since the difference of velocity between the centre and circumference of the screw produces a circulation within the fan itself, as shown in Fig. 26. The loss due to this circulation is greater when, as in Fig. 26, it is the I.P.V. that is partially closed than when it is the L.P.V. To reduce the loss the centre of the airscrew is often covered with a disc to prevent the return flow; the volumetric speed for a given diameter and velocity is thereby decreased, but the mechanical efficiency is increased.

It is impossible to secure that all the energy given to the gas shall produce axial flow; some inefficient tangential and radial flow is always produced at the same time. In the Rateau screw fan, shown in Fig. 27, the tangential and radial flow are greatly reduced by throwing the gas to strike the blades (B) with a velocity opposite to that of their rotation. This velocity is imposed on the inflowing gas by the fixed vanes V. The centre of the blades is covered by the fixed disc D. a shows a transverse section through the fan, b a "cylindrical" section made by a cylinder coaxial with the fan, cutting B and V and developed into a plane. In b the motion of the blades B is upwards. The Rateau screw fan resembles in its performance a simple centrifugal.

Some fans, described as of "mixed flow," are intermediate between centrifugals and airscrews, the flow of gas being partly radial or tangential and partly axial. But they do not differ essentially in principle from the
many types of pure airscrews and centrifugal, which are also described in makers' catalogues, to warrant special notice. For small powers there seems little to choose between these classes of fans; for larger powers the centrifugal is more suitable; it is also more suitable for the individual members of a composite pump.

Bi. Thermal Pumps

§ (37).—The principle of these is sufficiently discussed under “Convection.” The chimney of the open fire which ventilates a room and the gas jet in the flow of the chemical flame of a capillary are familiar examples of “blowers” of this type. The draught produced by a flame in a flue has also been used to work small wind channels for aeronautical investigation; and generally, if only very small powers are concerned and efficiency is unimportant, chimneys and small fans may be regarded as mutually interchangeable.

C. High-vacuum Pumps

(General References (21), (23))

§ (38).—During the last few years pumps have been invented which will attain pressures definitely lower than those that can be reached with any of the pumps described so far. They depend upon “molecular” processes, that is to say, processes explicable by molecular theory and not by hydrostatic or hydrodynamical theories, which regard a gas as a continuous medium. These processes become important only when the pressure of the gas is below some definite limit, which is usually far below that of the atmosphere. The pumps must therefore be run in series with an auxiliary pump which reduces and maintains the pressure below the limit at which the action of the molecular pump begins; this pressure is of the order of 0.1 mm. As auxiliary pumps, those of type (Ad) are now usually employed. Further, since the vapour pressure of water is much above the limiting pressure, a drying agent must be used in conjunction with the auxiliary pump; on the other hand, a molecular pump does not distinguish between vapours and permanent gases, and no device is needed to remove from the low-pressure side of the pump any vapours except those which arise from the action of the pump itself.

Two molecular processes have been employed for such pumps, both originally suggested by Gaede. Since the first type was the only member of its class when first invented, it was called by its inventor the “molecular pump.” It is convenient to retain the term and confine it to this type, although the second type, invented later, has an equal right to it.

CJ. Friction Pumps

§ (39). GASEOUS MOLECULAR PUMP.—The action depends upon the forces between a gas and a solid (or liquid) surface moving relatively to it. At ordinary pressures these forces are determined by the viscosity of the gas, and the influence of the solid boundary enters into the calculation of the flow only through the assumption that the velocity of the gas at that boundary, is zero and that there is no “slip.” But at sufficiently low pressures Knudsen and Warburg (15), confirmed by many later observers, showed that the measured flow agreed with that predicted hydrodynamically only if it was assumed that there is some slip, that is, the velocity of the gas at the boundary and parallel to it, is finite, and that the force exerted on the gas by the boundary is \( \epsilon \rho \). \( \epsilon \) is called the friction coefficient and \( \rho \) the coefficient of slip.

From the molecular standpoint the matter appears somewhat differently. The condition \( \rho = 0 \) means that the velocities of the molecules leaving the boundary are symmetrical on either side of the normal. The appearance of slip at low pressures does not mean that this condition is no longer fulfilled. For if the pressure is greater on one side of the normal than on the other, more molecules will arrive at the boundary from the first side; if the molecules leave the boundary equally distributed on both sides, there will be on the whole a flow of gas from the first side to the second, so long as the distance travelled by the molecules leaving the boundary before they collide is finite. On the other hand, the flow will be less than it would be if the molecules left the boundary with their velocity parallel to it unchanged. Accordingly the condition \( \rho = 0 \) is not inconsistent at low pressures with the hydrodynamical assumption of a finite slip coefficient.

Knudsen (16) has calculated the friction coefficient from such a molecular theory. He assumes that whatever the direction of the incident molecules, the number with any velocity leaving the boundary within a cone of solid angle \( d\omega \) making an angle \( \theta \) with the normal is proportional to \( \cos \theta d\omega \) and that the distribution of velocities is Maxwellian. He concludes that

\[
\epsilon = \frac{\rho}{\rho_0} \sqrt{\frac{\pi}{2}} \sqrt{\frac{Z}{M}} \theta \quad \cdot \quad \cdot \quad (31)
\]

and \( \rho_0 \) is the density of the gas at unit pressure and the prevalent temperature. (31) has been confirmed by experiments at pressures less than 0.001 mm. Gaede (17) has shown that at higher pressures \( \epsilon \) is greater, probably owing to the presence of a gas film on the bounding surface.

Consider a layer of gas between two infinite
parallel plates, distant $h$ from each other, moving relatively to the gas with velocities $v_1, v_2$. Let $p_1, p_2$ be the pressures of the gas at points distant $L$ along the direction of motion. If the pressure is so high that the mean free path is small compared with the distance between the plates, the forces on the gas are due to its viscosity; the relation between $p_1$ and $p_2$ is given by the equation similar to that of Poisson:

$$p_1 - p_2 = \frac{\epsilon_0}{\kappa^2} \cdot L(v_1 + v_2). \quad (32)$$

But if the distance between the plates is small compared with the mean free path, the conception of a viscosity depending on collisions between molecules becomes insignificant, and the equation must involve only $v$, depending on collisions with the wall. It is found that

$$\log \frac{p_2}{p_1} = \frac{\epsilon_0 L v_1 - v_2}{K}. \quad (33)$$

The ratios of the pressures at opposite ends of the plates is a function of the velocities and of the geometrical quantities: it is independent of the pressures. If any geometrical arrangement other than that of parallel plates is used, this proposition is still true, so long as the pressure is sufficiently low, and as long as the velocities are considerably less than the mean velocity of the molecules. If this last condition were not fulfilled the distribution of velocities among the molecules leaving the boundary would be no longer Maxwellian, and $\epsilon_0$ would be greater—which would clearly be desirable for the purpose in view.

Fig. 29.—The construction of Gaede's pump (16) in which this principle is applied is shown diagrammatically by transverse and longitudinal sections in Fig. 28. A is a cylinder rotating in the closely fitting housing $B$; in the surface of $A$ are cut grooves into which project the obstruction $C$ attached to the housing; the pipes $n$ and $m$ open into the grooves on either side of $C$. If $A$ rotates clockwise the friction between the rotating cylinder and the gas lowers the pressure at $n$ and increases it at $m$. The grooves are in series from the middle outward; $m$ of the middle grooves is connected to $n$ of each of the grooves on either side, and so on; $m$ of the outermost grooves are connected to the auxiliary vacuum (H.P.V.) and $n$ of the middle groove to the L.P.V. A is run at about 140 revs. per sec. by a pulley and motor. The axle passes through an oil box which seals the interior of the housing from the atmosphere. The intrusion of oil from the oil box is prevented by an Archimedean screw cut on the axle, which drives the oil backward; this arrangement makes it of great importance that the auxiliary vacuum should be turned on after the pump is started, and turned off before it stops.

The precise calculation of the pressures obtained is very complicated; for there has to be taken into account, besides the driving of the gas from $n$ to $m$ by the friction of the rotating cylinder, the leak of the gas back from $m$ to $n$ past the obstruction $C$ and over the surface of the cylinder between successive grooves. But theory shows and experiment confirms that at a sufficiently low pressure the ratio of initial and final pressures is proportional to the speed of rotation and independent of the pressure, but the ratio falls off when the pressure in any part of the pump rises above that (about 0-06 mm.) at which $b$ is equal to the mean free path. At a speed of 140 revs. per sec. and an auxiliary vacuum of 0.1 mm. $p_2/p_1$ is about 10, so that a pressure of $10^{-4}$ mm. can be obtained. But the ratio varies with the gas, in virtue of the occurrence of $\epsilon_0$ in (31); it is less with hydrogen than with air; probably hydrogen formed a large part of the gas with which this measurement was obtained. Lower pressures could be obtained with a better auxiliary vacuum; but the vacuum attainable is definitely limited by that of the auxiliary pump.

An important feature of these pumps is the great speed of pumping. Fig. 29 shows $S$ (in cm.$^3$/sec.) plotted against the pressure (log scale); for comparison $B$ shows $S$ for the Gaede rotary mercury pump (A).

The molecular pump would have made possible modern high-vacuum work; but all its advantages, except one, are possessed by the next type of pump to be considered. This one advantage is that it will remove all
vapours, while all other high-vacuum pumps leave mercury vapour, which has to be removed by condensation. But the advantage is of little practical importance for most work since the pump will maintain the vacuum only while it is running; if it is to be stopped and the vacuum preserved, some form of tap or trap must be inserted, and such devices always introduce vapours. On the other hand, the molecular pump is necessarily expensive and requires skilled attention. Despite its novelty and ingenuity it is already practically obsolete.

**8. Diffusion Pumps**

§ (41) **Diffusion Pumps.**—In Fig. 30 (a) let \( X \) be the H.P.V. in which is maintained a constant pressure, \( L \) the L.P.V. to be evacuated. Let \( X \) be a vessel in which some liquid can be heated, while \( H \), but not \( L \), is cooled so as to condense its vapour. If the liquid is heated to a temperature at which its vapour pressure \( P \) is large compared with \( P_0 \), a continual stream of vapour will pour along the tube \( XMH \), driving the gas before it and condensing in \( H \); if the stream is sufficiently rapid the gas in \( H \) will be unable to diffuse back into the tube against it. On the other hand, the gas in \( L \) will diffuse out into the vapour stream and be carried by it into \( H \). For this diffusion is not opposed by a vigorous stream in the contrary direction; since \( L \) is not cooled, the vapour will not condense in \( L \) and vapour will enter it only at a rate sufficient to replace the gas diffusing out. Accordingly, after some time \( L \) will be completely evacuated of gas and contain only vapour. If \( L \) is now cooled, the vapour will condense and an almost perfect vacuum be left in \( L \). The vacuum will not be quite perfect because some gas from \( H \) will diffuse back against the stream of vapour, however low is \( P_0 \) and however rapid the stream; but a consideration of the magnitudes involved will show that the residual pressure could easily be made inappreciable.

Such is the principle of the diffusion pump in its simplest and ideal form. In practice it is impossible to maintain the whole of \( L \) (the apparatus to be evacuated) at or above the temperature of the boiling liquid during the evacuation. \( L \) as well as \( H \) is cooled sufficiently to condense the vapour, and consequently if the simple arrangement of Fig. 30 (a) were adopted, the diffusion of gas out of \( L \) would be opposed by a vigorous stream of vapour entering; if the gas from \( H \) could not diffuse against the stream neither could the gas from \( L \); there would be no pumping. Some devices, therefore, must be adopted to prevent a stream of vapour entering \( L \).

§ (42) **Garde Diffusion Pump.**—The device originally adopted by Garde (19) was to place in the tube leading to \( L \) an obstruction with a very small opening. If the linear dimensions of this opening are small compared with the mean free path of the molecules, the laws of the flow of gas and vapour through the opening are not those of hydrodynamical streaming, but those of diffusion. The flow depends on the partial pressure of the constituents of the mixture and not on their total pressure. Since the partial pressure of the gas in the tube \( XMH \) is zero, the gas will diffuse out through the entering vapour in spite of the fact that the total pressure of the vapour is greater in the tube than in \( L \). The problem can be treated exactly by molecular theory. If \( d \) is the diameter and \( s \) the area of the opening at \( M \), \( \lambda \) the mean free path, \( P_0 \) the density of the gas at a pressure of 1 dyna per sq. cm., then the volume of the gas, measured at \( P_0 \), issuing through \( A \) per sec., is given by

\[
S = 4\pi \frac{e^2}{2\pi P_0} \quad \ldots \quad (34)
\]

where

\[
e = \frac{e^2}{2} - \frac{1}{2} \ln (x + e^2), \quad \text{and} \quad x^2 = d^2/4.
\]

\( e \) attains the maximum 1 when \( d/\lambda \) is small; but \( e \) decreases with \( d \). The maximum value of \( S \), when \( \lambda \) is fixed, is given approximately by \( d=\lambda \). This maximum will increase with \( \lambda \), since the vapour pressure of the liquid must be greater than \( P_0 \), is limited by \( P_0 \). Accordingly the speed of the pump depends greatly on the auxiliary vacuum, and also on the temperature of the liquid. For if \( P \) is too small, gas will diffuse back from \( L \); if \( P \) is too large, the diffusion of gas from \( L \) will be hindered by the opposing flow. The conditions in the pump need therefore careful adjustment. On the other hand, \( S \) is independent of the pressure of the gas and dependent only on its nature and temperature; this is the most striking feature of all diffusion pumps. \( S \) is greater for the lighter gases; the variation of \( S \) with the nature of the gas is the contrary of that for the molecular pump.

§ (43).—Any liquid could be used in a diffusion pump, so long as it could be maintained at the appropriate temperature. Actually mercury is used, for the appropriate temperature is convenient \((T=0^\circ \text{C.})\).
moreover it is chemically stable and does not wet glass. But its universal adoption is probably due in part to the previous association of mercury with air-pumps—an association based on quite different properties.

The vapour of the liquid used in the pump at the pressure corresponding to atmospheric temperature is left by the pump in L. It is easily removed from the apparatus connected to L by making the connection through a trap cooled in liquid air. The introduction of the cooled trap involves, of course, a continual stream of vapour opposing the diffusion of the gas through L; but at atmospheric temperatures the vapour pressure of mercury is so low that the consequent diminution in the speed of the pump is inappreciable. However, Gaede (10) has pointed out that the existence of this stream causes a slight error, appreciable at the lowest pressures, in the measurement of the pressure in L by a McLeod gauge. Since vapour is issuing from the gauge to L the pressure of the gas in L is slightly higher than its pressure in the gauge.

§ (44).—The original diffusion pump of Gaede involved complicated glass construction; since it is no longer used, it need not be shown. The maximum value of S obtainable was about 80 cm. and far below that of the molecular pump at the higher pressures. On the other hand S was, as theory predicts, independent of the pressure down to the limits of measurement; at pressures less than 10-4 mm. the diffusion was as good as the molecular pump, and no practical limit to the pressure was set by the diffusion of gas from H against the vapour stream.

Moreover, it should be observed that there is nothing in the principle of the pump to limit its use to very low pressures, except the condition that \( d > \lambda \); if openings as small as the free path could be obtained at atmospheric pressure the pump would work. Gaede has actually used the pump at atmospheric pressure, taking the pores of an earthenware pot as the openings and steam as the vapour; but since the pores are backed by very fine tubes, through which the gas has to flow before it arrives at the pump, the speed of such a pump is very slow; it is not generally of practical use.

§ (45). LANGMUIR "CONDENSATION" PUMP.

A simpler and more efficacious method of preventing the flow of vapour into L is to use the inertia of the stream to carry it past the opening. Thus in the modification shown in Fig. 30 (b) if the velocity of the stream of vapour issuing at C is as great as the velocity of the molecules in the stream, all the vapour will travel forward till it meets the walls of the outer tube or the gas in H; none will stream towards L and prevent the diffusion of gas from L, although the pressure in the vapour stream, as measured by its density, may be very much greater than the pressure in L. It will be seen that the construction is similar to the gas injector pump B, but the principle of action is different. The gas from L diffuses against the hydrostatic pressure; it does not flow with it.

If the walls of the outer tube were heated by the vapour, the liquid condensing on them would have a vapour pressure greater than that in L; there would be a flow of vapour from the heated walls towards L, which is cool, and this stream would once more hinder the diffusion of gas from L. Accordingly Langmuir (20), who first used this arrangement, had great stress upon the cooling of the walls struck by the vapour stream; he insisted that the vapour must be immediately condensed to the temperature prevailing in L, so that there should be no flow of the vapour back towards L. On account of the import once attributed to this condensation, he termed his pump a "condensation" pump to clinch goth it from Gaede’s diffusion pump; but i is equally a diffusion pump in the sense that the gas from L follows the gradient of partial pressure, not that of total pressure. Gehrt (21) has pointed out that Langmuir’s principle was anticipated by Magnus (22), who did not see its applications.

It appears, moreover, that though the very efficient cooling of the walls and the complete condensation is necessary to the most efficient working of the pump, it is possible to make a pump of this type with much less efficient cooling. This is achieved in Crawford’s parallel jet pump (24). But in its working characteristics this pump resembles the diffusion rather than the condensation pump, and has not the advantages of Langmuir’s pump noted below.

§ (46).—The construction of Langmuir’s pump in metal (25) is shown in Fig. 31; it can also be made without great complication in glass (26). The mercury M is maintained at temperature of about 100° C. by the expenditure of about 300 watts, supplied electrically or by a burner. The baffle B deflects the vapour stream downwards and against the walls cooled by the water jacket J. T I L.P.V. is connected to L; the auxiliary pump to H. If this pump maintains pressure \( p_H \) of 0.01 mm. or less, S is as great as 3000-4000 cm. 2/sec. and is, as before, dependent of \( p_H \) down to the lowest accessible pressures. Higher pressures \( p_H \) decelerate the speed, but the pump will work even the pressure is nearly 0.1 mm. The speed is independent of the temperature of \( T \); however, so long as this is above a limit which is greater the greater is \( p_H \). The speed of the pump—greater even than the maximum of the molecular pump—and
absence of any need for the accurate control of temperature, are the advantages that have caused condensation pumps to replace wholly the original Gaede type.

Many variations on the original Langmuir design have been made. In some of them (20, 27) the heating of the mercury is effected by an arc maintained between two mercury surfaces inside the pump; in fact this arrangement has been applied to large mercury-vapour current rectifiers (28), so that the rectifier acts as its own high-vacuum pump, only an auxiliary pump being needed. Again, it has been proposed (29, 30, 31) to combine in the same apparatus a mercury-vapour jet pump and a condensation pump, using the same stream of mercury vapour. The two act in series, and the combination will work with an auxiliary vacuum of 10-20 mm.; but the construction is complicated.

However, special reference need be made only to one type of this pump, remarkable for its simplicity. It is found possible to dispense altogether with the inner tube in Fig. 30 (b) and to make the arrangement of Fig. 30 (a) act as a condensation pump by merely cooling the walls of the horizontal tube. Since the mercury molecules striking the cooled walls do not rebound therefrom, if the cooled tube is made sufficiently long, all the molecules emerging from its end at M will be moving parallel to the length of the tube and will not enter the side tube. One form of such a pump is described in (32). An even simpler construction is shown in Fig. 32 adopted, the whole being made of sheet metal. The limit of $p_0$ at which the pump will work is about 0·015 mm., and somewhat higher than that for the Langmuir type. But the value at which the maximum speed is obtained is not very different; this maximum is about 1500 c.in.²/sec., and is set by the dimensions of the inlet tube (see below) rather than by the pump itself. The auxiliary vacuum of 1 mm. for this or the Langmuir pump can be obtained by oil-pumps, and presents no difficulty. The simple pump of Fig. 32, as well as the Langmuir and other more complicated pumps, is used on the industrial scale in the manufacture of thermionic valves and other high-vacuum devices.

§ 47. High-vacuum technique. It has been pointed out that there must be some limit to the pressure reached by a diffusion or condensation pump, determined by $p_0$ and the speed of the vapour stream. When a high-vacuum pump is used the pressure attainable and the speed of pumping are actually limited by factors other than the efficiency of the pump. In the first place, the tubes connecting the pump to the apparatus offer a resistance to the flow of gas. Kundt (10) has shown that the volumetric speed of a perfect pump is given by

$$S = \frac{1}{\sqrt{p_0} R},$$

where $R$ is a constant dependent on the form of the connecting tube and $p_0$ is the driving pressure.

![Fig. 31](image)

![Fig. 32](image)
Eventually, the speed has to be slowed by the temperature, at which point the atmosphere begins to collapse. The gas at high pressure is also necessary to be maintained indefinitely if the vessel is gas-tight. But if the vessel is gas-tight, it is necessary to seal it off, eventually, which is possible by the sealing, as quickly as possible. After this has been accomplished, the vessel is immediately freed from all gas, and the gas, if any, is no longer contained in the vessel. The gas from the vessels is largely lyophilized and absorbed from the gas by the system.

The gas from the vessels is largely lyophilized and absorbed from the gas by the system. The gas from the vessels is largely lyophilized and absorbed from the gas by the system.

AIR-PUMPS

the inactive group, to form solid compounds with low vapour pressures. But some of the compounds, especially the hydrides, have considerable dissociation pressures at slightly higher temperatures, and the temperature of the metal must be carefully controlled. The method has its uses in special circumstances (e.g. where high vacua have to be maintained away from a laboratory or supply of liquid air). The alkali metals will also combine with all active gases; the combination is usually brought about by the electric discharge. It has long been known that a discharge passed with a cathode of sodium or potassium (more conveniently the alloy of the two) will remove the common gases down to the pressure where the discharge ceases. The latest development in this direction is absorption by heated thorium or zirconium (35).

§ (52) Absorption. — But such chemical methods have been little practised since the discovery of the powerful absorption for gas of charcoal at low temperatures. From the discovery of the method by Doxar (30) to the invention of the molecular pump in 1913, it was the standard method of producing extreme vacua unattainable by liquid piston pumps. A glass or preferably silica tube containing a few grams of charcoal is attached to the vessel to be evacuated. The charcoal is heated during the preliminary exhaustion of the vessel, which should be carried to 900 C.; the vessel is then disconnected from the pump and the charcoal tube cooled in liquid air. If the vessel is large and the highest vacuum is required, two or more charcoal tubes may be attached, one being sealed off before the next is cooled.

Many experiments have been made on (1) the relative amounts of different gases which charcoal will absorb at different temperatures and (2) the absolute amounts absorbed by charcoal prepared in different ways. A full discussion of the results is beyond the scope of this article, and for fuller information reference may be made to a good summary in (37).

As regards (1) it appears that, in general, gases are more absorbed the higher their boiling points, the exception being the inactive gases which are but slightly absorbed. The mass absorbed is proportional to the mass of the charcoal; it increases as the temperature is decreased and as the final pressure of the residual gas is increased; it is doubtful, therefore, whether a really perfect vacuum could be obtained by the method in ideal conditions, but, as with the diffusion pump, the actual limit lies beyond the range of measurement. The rate of absorption decreases gradually as the equilibrium pressure is attained, and, though the speed of evacuation is rapid compared with that of any piston pump down to 0001 mm., it is probably slower than that of the Langmuir pump at lower pressures.

As regards (2), there is some conflict of evidence which has been only partially removed by the very complete study of the absorption by charcoal which resulted from its use in gas masks during the late war. In general the denser charcoal from the harder woods shows the greater absorption; the shell of the coconut and the kernels of some fruits are the best raw materials. The original charcoal should be at a temperature not exceeding 900 C., and must be followed by some process for the removal of hydrocarbons. For this purpose heating in a stream of chlorine at 800 C followed by heating at the same temperature in hydrogen has been suggested; but the best modern practice appears to be alternate absorption of air or oxygen at atmospheric pressure and liquid air temperature with "cooling" of the absorbed gas by evacuation at 400-500 C. Some writers maintain that all absorbed gases can be removed by heating to 900 C., others that heating to any temperature over 500 C impairs the subsequent absorption. It has been found also that charcoal, activated by special processes, will produce high vacua even in atmospheric temperature.

Absorption, similar to that of charcoal, displayed by other finely divided solids. In fact, all solids probably absorb some gas at a temperature, the differences are merely of degree. Of the other solids proposed for practical evaporation, palladium black (which will absorb other gases as well as hydrogen) and finely divided copper may be mentioned. In addition reference may be made to the usually great absorption of hydrogen by tantalum at atmospheric pressure. Here again reference may be made to (38).

§ (53) Absorption in the Electrical Discharge.—In the early study of X-rays it was found that a hard tube often became "harder" by the passage of the discharge through it in consequence of a disappearance of part of the residual gas. This disappearance seems to be a normal accompaniment of the discharge when it does not take place, or when the contrary process of an evolution of gas occurs, it is because the normal disappearance is obscured by an evolution of gas caused by heating or possibly by some other and distinct action of the discharge.

The facts concerning this absorption of gas are still obscure, and still more obscure explanation of them. It is certain that inactive gases are in general less absorbed than others, but whether and to what extent nature of the electrode and of the vessel determine the absorption is not yet certain. Here reference will only be made to those actions of the discharge in "cleaning-up"
gas which are of practical importance. A general reference may be given to (39).

The final evacuation of such apparatus as thermionic valves, rectifiers and X-ray tubes is probably effected by the discharge. However carefully the apparatus is evacuated by pumping, some gas is always introduced in sealing off from the pump. This gas is largely, if not entirely, absorbed by the walls and electrodes before any discharge passes; but during the first few moments of the discharge, which represents the normal function of the apparatus, some further change occurs which makes the "clean-up" more complete and more permanent.

It has long been known that the passage of the discharge between suitable electrodes would promote chemical actions which lead to the removal of gas. An instance is provided by the discharge between electrodes of the Hall tubes, which has been already mentioned. Again, it has been found that a discharge passing to an electrode of charcoal would cause the charcoal to absorb at atmospheric temperature as it will absorb without the discharge at liquid-air temperature (40).

§ 54. — But the most practically important process of evacuation dependent on the discharge is that which involves the introduction of phosphorus vapour into the evacuated vessel. It appears to have been discovered first by Mulligan (41); it was applied to the evacuation of electric incandescent lamps and has been used for the same purpose continuously since its discovery. At first it appears to have been thought that the action was chemical, but it is now known to be dependent on the passage of a discharge through the mixture of gas and containing phosphorus vapour.

The exact conditions which determine the disappearance of the gas are still obscure, but it may be stated generally that if a discharge is passed through any mixture of gas or vapour containing phosphorus vapour the pressure will be reduced more rapidly and to a lower limit than it would be if the phosphorus vapour were absent. The gas that has disappeared can be restored by heating the walls of the vessel to a temperature at which red phosphorus will evaporate. The latest theory of the action (42) is that the gas is deposited on the walls and covered with a "varnish" of red phosphorus produced by the action of the discharge from the phosphorus vapour, which prevents the re-evaporation of the gas so long as the "varnish" remains; it is also supposed that the exceptional electrical properties of the phosphorus vapour are of importance. It is known that sulphur, iodine, and arsenic act in somewhat the same way as phosphorus in this matter.

In an incandescent lamp the necessary

discharge passes between the opposite ends of the filament which not as electrodes, the filament, being incandescent, gives a thermal emission sufficient to abolish the cathode fall of potential and permit a discharge to proceed even when the potential difference between the electrodes does not exceed fifty volts.

In Mulligan's original method the phosphorus vapour was introduced by heating a small quantity of red phosphorus in the tube, connecting the lamp to the pump just before sealing off. The later practice is to deposit the red phosphorus on the filament or the adjacent supports, whence it evaporates as soon as the filament is heated. Nowadays it is also usual to deposit on the filament, together with phosphorus, salts such as fluorides or chlorides. Various benefits are attributed to the presence of these salts, but it seems to agree that their action is subsidiary to that of the phosphorus, and that the evacuation would not occur unless phosphorus (or one of the other elements mentioned) were present.

By this process of phosphorus evacuation the use of high-vacuum pumps in lamp manufacture is rendered unnecessary. If the lamp leaves residual gas at a pressure of 0.1 mm in the lamp, almost all this gas will be removed in the first few seconds of "burning," and the pressure reduced to less than 0.001 mm. No mercury-pumps are now needed in lamp-making; oil-pumps, usually of the classical type, are sufficient.

The same method has been applied to other commercial vacuum apparatus, e.g. rectifying valves of the old type without an incandescent cathode (43), and, more rarely, to the modern thermionic type.

BOMBS CALORIMETERS

§ (1) Introduction. — The laboratory method of determining the caloric value of a fuel is to burn a known weight of a carefully dried sample in a vessel containing oxygen. From the temperature rise of the water in the calorimeter the heating value of the fuel is computed, taking into account certain corrections which are described later. Although the caloric value does not give all the information desired concerning a particular fuel, or determine its suitability for a specified purpose, yet it is generally accepted that the heating value is the most important property to be considered in estimating the value of fuel. Purchasers of large quantities of coal now adopt the heat-unit tests of evaluation, and the technique of combustion calorimetry has been so well developed that a skilled operator can average thirty-five determinations per day.

Two types of apparatus are employed for such tests. In one the fuel sample is burned under normal atmospheric pressure in a calorimeter of the "submerged bell" type, whilst...
Calorimeters

In the other the fuel is burned under high pressure in a "bomb" type of calorimeter. Some authorities prefer the "bell" type to the "bomb" because in the latter the combustion is carried out in oxygen at nearly atmospheric pressure and, consequently, the conditions resemble those obtained in steam boiler practice. With a "bomb" calorimeter the combustion is almost instantaneous and resembles an explosion in its violence and rapidity.

The decomposition products of coal vary somewhat, and it is generally found that the results obtained with the bomb calorimeter are slightly higher than those with the "bell." For scientific work, however, the bomb type is universally used, since under good working conditions the combustion obtained is practically complete. In skilled hands either method gives reliable and concordant results for solid fuels, but the "bomb" is the only method applicable to liquid fuels.

§ (2) Description of a Bomb Calorimeter Outfit.—The calorimetric outfit consists of the following elements:

(i) The bomb.
(ii) The calorimeter vessel, stirrer, and constant temperature jacket.
(iii) The temperature measuring instrument.

(i) The Bomb.—In one of the oldest forms of apparatus—the Mahler-Donkin—the bomb consists of a massive gun-metal cylinder provided with a cover held down by three studs. The cover is provided with a milled-head screw valve for regulating the inlet of oxygen to the cavity inside the bomb. The joint between the bomb proper and its cover is effected by means of a lead washer inserted in a circular groove. The inside of the cover has a projecting ring which registers with this groove when it is screwed down. The bomb is plated inside with gold in order to withstand the corrosive action of the nitric and sulphuric acids produced by the combustion of the fuel. The most satisfactory form of lining is that of platinum, but nowadays it is not much used on the score of expense. Porcelain annular is also sometimes used for lining the bomb.

The Kroocker type of bomb has a cover screwed on to the bomb (see Fig. 1). The bomb is made of steel and has a fixed platinum lining, while the cover is of bronze.

Parr¹ has recently designed a bomb of an acid-proof base-metal alloy which appears very promising.

Some investigators employ a replaceable lining, but in practice it is found difficult to maintain a perfect fit and, consequently, difficulties arise owing to leakage of the products of combustion into the space behind the lining where it corrodes the metal of the body of the bomb.

The staff of the U.S. Bureau of Mines has developed a form of bomb (see Figs. 2 and 3) in which the lid is held in position by a novel form of sealing device. This consists of a tough steel receiving nut and lock so constructed that less than a one-eighth turn with the wrench suffices for securing. A circular gasket of electrician's solder effects the seal. This locking device is an adaptation of the principle used in the breech locks of artillery. They claim for this design durability, ample strength, and facility of manipulation. Further, when the lock wears out a new one can be substituted without the expense of making and gold-plating a new shell. The shell of the bomb is made of Monel metal which is well adapted to gold plating.

Frey has devised a bomb calorimeter in which the heat developed is shown on an indicator. See article on "Calorimetry, Method of Mixtures," § (13) (ii), "Metallic Block Calorimeters." (ii) The Calorimeter, Stirrer, and Constant

Temperature Jacket.—In the outfits employed in this country the calorimeter, stirrer, and jacket are similar to those employed in apparatus for ordinary calorimetric experiments by the Method of mixtures (see § (4)).

At the U.S. Bureau of Mines, a form of apparatus has been developed which is especially adapted for combustion calorimetry (see Fig. 4).

The calorimeter is made of heavy sheet brass reinforced at the top and middle by brass bands (see A). A tubular stirrer well is inserted in the calorimeter as shown in B. An embroiler is fastened to the bottom of the calorimeter, but insulated from it, which makes contact with the bomb plug when this is placed in position.

The calorimeter is supported in its jacket on three ivory studs. The jacket is a cylindrical vessel provided with a cover of brass ground to a water-tight fit. This cover is provided with a thin sheet-brass water seal (see Fig. 4) fixed to the cover proper by means of three thin insulating rods of ivory in such a manner that when the calorimeter is in place and the cover brought down snugly the water seal is in contact with the surface of the water in the calorimeter, thus serving as an effective seal against evaporation into the space between the calorimeter and its jacket.

Soldered to the jacket are two heavy brass lugs, by which it is held to the vertical T-bar of the frame in such a manner as to permit the jacket to slide vertically. The jacket is supported by a heavy helical brass spring bearing against the bottom of the tank, and of such strength that the jacket when cooled is held vertical with its top slightly above the surface of the tank water against an adjustable stop fixed to the T-bar.

The stirrer shaft arrangement is also shown in Fig. 4. The upper part of the shaft (C) which the driving wheel is mounted consists of a thick-walled brass tube, into which the lower part of the shaft telescopes, the latter being provided with a conical piece (D) screwed to the end which engages a receiver at the lower end of the shaft tube after the manner of a conical friction clutch when the whole calorimeter is lowered into place. The lower bearing of the stirrer shaft is carried by the lid bracket (D), which is held to the vertical T-bar of the frame by a clamp which permits of raising and lowering the lid and clamping in any desired position.

The calorimeter cover has tubular outlets (not shown in Fig. 4) for the thermometer, the stirrer shaft, and electrical leads, so that the jacket and its cover may be totally immersed in the tank water during an experiment.

In the equipment of the Bureau six of these outfits are mounted in one thermostatically controlled constant temperature bath.

(b) The Temperature Measuring Instrument.—With the majority of bomb calorimeters outfits mercury thermometers are employed for the measurement of the temperature of the water. Such instruments have the advantages of simplicity, cheapness, moderate accuracy. They have the disadvantage of considerable lag and lack of sensibility required for work of the highest precision. The mercury thermometer, moreover, possesses the serious drawback that the mercury often sticks in the bore, particularly with a falling manometer. This trouble can be somewhat alleviated by tapping the thermometer and some observers utilise a miniature electric buzzer for this purpose.

The thermometer should preferably be a solid stem type with its scale divided to 0.02° C. and the scale divisions should extend down to the bulb to avoid uncertainty as to the magnitude of the encycrystal column.

For work of the highest precision a electrical resistance thermometer is necessary, and a description of suitable instruments for the purpose will be found in the article on "Resistance Thermometers." § (6 (3)).
§ (3) METHODS OF CONDUCTING A TEST.

(1) Calibration of the Apparatus.—It is necessary to determine the heat capacity of the bomb and its fittings by experiment, since it is nearly possible to calculate this constant from the specific heat of the materials employed in its construction. There are two standard methods of effecting this calibration:

(a) By an electrical method based on the input into the calorimetric system of a known amount of heat measured as electrical energy.

(b) By burning substances of known heating value.

The electrical method is capable of considerable accuracy, since electrical energy can be measured with high precision. In practice, however, the method suffers from the disadvantage that it involves elaborate equipment and is time-consuming. Further, it is by no means easy to reproduce with it the same conditions as prevail during a combustion test. The electrical method is generally adopted in standardizing laboratories, but for the purpose of a works laboratory the second method is to be preferred.

(b) To calibrate a calorimeter by means of standard substances, such as naphthalene or benzoic acid, it is advisable to make about half-a-dozen combustions, sufficient amounts of the standard being used to produce about the average temperature rise obtained in tests with coal. This method, besides being simple and easy of application, tends to minimise errors such as those due to thermometer calibration, cooling correction, heat input from stirring, etc. Dickinson has recently redefined the heat combustions of the following substances: naphthalene, benzoic acid, and sucrose or cane sugar, with a view to their adoption as standards in calibration work. His results are summarised in Table I, together with those of previous observers.

It appears from a comparison of the values given by different observers for the same substance that benzoic acid is the most suitable in view of the close agreement of the results obtained.

Dickinson found naphthalene to be a convenient material to work with, but care was necessary in handling since a gram briquette would lose about 1 milligram in weight per hour by sublimation. Sucrose did not seem so well adapted as benzoic acid for standardisation purposes. It has a smaller heat of combustion and frequently fails to ignite.

Dickinson suggests that the higher results given by other observers for sucrose may be due to the fact that they may not have corrected for the heat generated in the firing wire before the sample ignites. With sucrose a greater length of fuse wire has to be used than with other materials on account of its lower inflammability.

Iron wire is frequently employed because it burns instead of only melting, and is therefore more certain to ignite the sample. The heat of formation of iron oxide is about 1600 calories per gram of iron. The sucrose specimens required about 3 mm. of wire weighing 133 mg. per metre. Hence the correction for the heat liberated in its combustion amounted to about 2 calories per centimetre. Naphthalene ignited readily with 1 cm. of wire.

He also corrected for the small amount of nitric acid formed from the nitrogen contained in the oxygen. The amount is nearly proportional to the heat liberated in the combustion and to the percentage of nitrogen present, and was determined by titration after each combustion. The heat of formation of HNO₃ from N₂O₃+H₂O is about 230 calories per gram of acid. As the oxygen employed contained from 0.3 to 0.5 per cent of nitrogen, the correction to be applied for the heat of formation of HNO₃ was usually about 1 part in 1000.

§ (4) PREPARATION OF THE TEST SAMPLES.¹

(1) Solid Fuels.—It is necessary to convert the coal into a small briquette or tablet for the purposes of test. If the attempt is made to employ the sample in powder form the force of the explosion usually blows some of it against the internal walls of the bomb and it escapes combustion.

Bituminous fuels as a rule will form briquettes by pressure alone. In cases where insufficient tarry matter is present in the natural fuel, just sufficient of a 1 per cent solution of gum arabic may be used to make the particles of fuel adhesive. For half a gram of fuel, three drops of such solution are enough. The

The data in the above table are expressed in terms of the 15° calorie.
BOMB CALORIMETERS

Briquettes must be heated in an air bath to 110°C for at least four hours to expel the last traces of moisture thus introduced before testing in the calorimeter.

(ii) Liquid Fuels.—In weighing and transferring the liquid fuel to the bomb, care must be taken to avoid the use of small cylindrical blocks of pure cellulose. One of these blocks being burned under the conditions and with all the precautions necessary for solid fuel, the only difference being that a higher pressure is used, in order to obtain a greater supply of oxygen in the bomb. A blank test with the cellulose alone gives the necessary data for the calculation. As liquid fuels contain only traces of oxidizable elements no trouble arises from combustion, and a bomb provided with a gold lining will last for a number of tests.

As regards the special precautions necessary to obtain correct results when testing liquid fuels, it must be pointed out that the absorbent cellulose blocks used for this purpose absorb moisture as well as oil, and that it is necessary to dry them before use for one or two hours in the air-bath at 100°C. When saturated with heavy oils of high boiling-point they are also somewhat difficult to ignite, and it is advisable to place a little of the dry unsaturated cellulose in a loose condition around the platinum ignition wire in order to avoid failure of the test from this cause. As the cellulose blocks are large in proportion to their weight and absorbent capacity, a larger platinum dish will be required than for the tests with solid fuel, and the platinum ignition wire should be arranged to hold down the cellulose block lest the explosive violence of the combustion blow it out of the dish.

§ (5) QUANTITY OF OXYGEN REQUIRED.—The quantity of oxygen required is about three times that which will unite with the charge to give complete combustion. Dickinson found that, when the amount of oxygen was much less than two and a half times that required to unite with the combustible charge, there were cases of incomplete combustion as indicated by a reduction in the total heat liberated, as well as by the occasional presence of a slight amount of soot and by the odour of the products of combustion.

Since the usual pressure employed in routine tests is 20 to 27 atmospheres, or 300 lb. to 400 lb., it is advisable to have a small check-pressure valve inserted in the milled-head screw in the bomb cover in order to avoid a great loss of gas when disconnecting the oxygen supply pipe and gauge from the bomb, after filling the latter with oxygen. At these high pressures the combustion of the coal is practically instantaneous, and the thin platinum wire used for ignition purposes generally is found fused owing to the temperature momentarily attained. In order to test the platinum capsule or crucible from this source, and from the action of the product produced, it is necessary to use a thin asbestos board, cut and shaped to fit the capsule or crucible. This asbestos board must be dried and ignited before use in order to remove all matter that might vitiate results.

§ (6) CALORIMETRY BY COMBUSTION V SODIUM PEROXIDE.—Fusion with sodium peroxide is the only way known for fixing the heat of oxidation of elements which are not born in oxygen and which form insoluble in acids. The method is applicable to the determination of the heat formed by the oxides of a metal and also the combination of metallic oxides with sodium peroxide.

The method is indirect and the heat evolved is not the observed effect; in burning compressed oxygen is formed, where possible, and hydrogen, when coal is burned with sodium peroxide the observed heat is the result of the following reaction:

\[ 2Na_{2}O_{2} + C = Na_{2}CO_{3} + Na_{2}O \]

The method is indirect and the heat evolved is not the observed effect; in burning compressed oxygen is formed, where possible, and hydrogen, when coal is burned with sodium peroxide the observed heat is the result of the following reaction:

\[ 2Na_{2}O_{2} + C = Na_{2}CO_{3} + Na_{2}O \]

Moreover, many substances do not give sodium peroxide sufficient heat to fuse the mixture, and hence some readily combustible substance, such as sulphur or carbon, is added which gives in many cases the true part of the total heat effect. Professor Mix of Yale University, who has made an extensive study of this method, gives the following results obtained by fusion with sodium peroxide compared with these by combustion of oxygen. They are:

</tbody>
</table>

Both values for C + 2O are for nearly carbon. One reason for the higher
found in the sodium peroxide method is that the carbon and peroxide were mixed in a mortar, thus allowing the peroxide to absorb a little moisture which added to the heat of the fusion. The value \(267.5\) for \(3F^2+4O\) is derived from the results of fusions of iron, ferrous oxide, ferric oxide, and the mineral magnesite with sodium peroxide, and 265.2 was the result of burning iron in oxygen.

Sodium peroxide absorbs very readily from the air, consequently it should be exposed as little as possible, as the hydrated peroxide will give more heat with a combustible than the anhydrous. One of two samples, that which gives off the less oxygen when fused, is the better one. The error from the water content is small in good peroxide. Its effect is further diminished when carbon, for example, is added to make a mixture fine, because in practice the heat effect of the carbon is found for the carbon and peroxide actually used.

Various substances may be added to a peroxide mixture to increase the temperature of the fusion. Mixture has been used acetylene carbon, sulphur, and lamp-black. Pure rhomboidal sulphur in fine powder would appear to be the best of the three, but it becomes electrified when shaken in the bomb with the other ingredients and sometimes sticks to the bomb and is not completely oxidised. Sulphide is formed and the reaction is free sulphur is left. When the bomb is much blackened by a fusion with sulphur the heat result is low. Acetylene carbon is the ideal substance to use, but difficult to obtain.

One part of the carbon requires 13 parts of pure sodium peroxide for combustion, and it is best to take about 20 parts in determining the heat effect of the carbon or lamp-black. For the combustion of sulphur double the calculated amount of peroxide should be used. Oxygen is often evolved in a combustion from the action of an acid oxide on the sodium peroxide, and the heat required to set it free from the peroxide is added to the observed heat. This correction, 1-72 g.-cal. for 1 c.c. of oxygen at 0° and 760 mm., is derived from Bekoffs’s No. + O = 100-26 Cal. and de Forcrand’s No. + 20 = 110-8 Cal.

Apparatus employed for the Tests.—The bomb is made of strolling silver whilst the top and fittings are of brass.

The mixture under test is contained in a cup of fine silver supported in the bomb by its upper edge. A fusion in the cup occurs more slowly than when in contact with the cold bomb, and hence the reaction is more complete.

The general arrangement of the apparatus is identical with that employed in final calorimetry with the addition of bulbs for collecting any oxygen set free by fusion. D. G.

CALORIMETRY

Calorimetry is concerned with the measurement of energy in the form of heat. It constitutes one of the most difficult branches of exact measurements owing to the fact that a perfect non-conductor of heat does not exist. The common method of measuring quantities of heat is by utilizing the different effects of heat on materials such as the change of
CALORIMETRY, ELECTRICAL METHODS OF

§ (1) GENERAL.—The electrical method of calorimetry was first employed by Joule with a view to the determination of the mechanical equivalent of heat \( J \). Subsequent work by Professors E. H. Griffiths, Schuster, Gannon, Callendar, and Barnes showed that the method was one capable of the highest precision for the determination of \( J \). The article on the determination of the mechanical equivalent \( \varepsilon \) of heat should be consulted for details of the method as applied to the determination of heat capacity of water and its variation with temperature.

In passing it might be mentioned that the calibration of bomb calorimeters is frequently carried out by electrical methods in which an equivalent amount of heat is obtained in combustion is generated in the bomb and its amount measured by observations of the water dissipated, the procedure being identical with that followed in methods for determining \( J \).

In specific heat determinations the great convenience possessed by the electrical method lies in the fact that it permits of the determination of true specific heats, i.e. the specific heat over a very narrow range of temperature, and consequently it has been of immense service in determinations of the variation of atomic heats with temperature.

§ (2) SPECIFIC HEAT OF LIQUIDS BY ELECTRICAL METHODS.—It is obvious that any of the appliances which have been devised for the evaluation of \( J \) are also applicable for the determination of the specific heat of liquids, and further that they would give data of the highest order of accuracy. There are, however, certain difficulties in practice.

Both Callendar and Griffiths applied their electrical methods for this purpose: the former determined the specific heat of mercury and the latter that of aniline.

§ (3) SPECIFIC HEAT OF MERCURY.—The apparatus employed by Callendar,\(^3\) Barnes, and

\(^1\) See "Heat, Mechanical Equivalent of."

Cook for the determination of the specific heat of mercury is shown diagrammatically in Fig. 1. The calorimeter differs from that employed for the determination of \( J \) in that the flowing mercury is the conductor in which heat is generated electrically and not a fine platinum wire stretched along the axis of the tube as in the case of the \( J \) apparatus. A steady stream of mercury flows through the fine capillary tube and is heated by a carefully controlled electric current. The difference of temperature between the inflow and outflow is observed by means of a differential pair of platinum thermometers. The inflow and outflow tubes AB and CD are exactly similar, about 2 cm. internal diameter and 25 cm. long. They are connected by the fine flow tube BC of 1 mm. in bore and 1 metre in length, coiled up in the form of a short spiral 2-5 cm. in diameter. The inflow and outflow tubes are provided with two side tubes, one pair for conveying the current, and the other pair for the mercury flow.

A practical advantage possessed by the continuous flow method is the fact that the heat less from the walls can be determined by making experiments with different rates of flow, but keeping the rise of temperature constant.

(1) Methods of determining the True Mean Temperature of Outflow.—By far the most important practical detail in this method is the device adopted for obtaining the true mean temperature of the outflowing liquid. If a thermometer were merely inserted in the outflow tube, leaving a free space all round for the circulation of the liquid, it is evident that the heated liquid would tend to flow in a stream along the top of the outflow tube, and that the thermometer might indicate a temperature which had little or no relation to the mean temperature of the stream. It is easy to make an error of 20 per cent in this manner. A fairly uniform distribution of the flow might be secured by making the space between the thermometer and the outflow tube very narrow. But this leads to another difficulty in the case of mercury. As the space is narrowed the electrical resistance is increased, and an appreciable quantity of heat, which cannot be accurately estimated, is generated in the vicinity of the thermomter.

The difficulty was overcome in the mercury experiments by fitting the inflow and outflow tubes with soft iron cylinders, 6 cm. long, turned to fit the tubes and bored to fit the thermometers. The soft iron had a conduc-
tivity about ten times that of mercury for both heat and electrici ty. The heat generated by the current in the immediate vicinity of the thermometer bulbs was so small that the errors might fairly be calculated from the difference of potential between the iron blocks at the middle points of the bulbs. The mercury stream was forced to circulate in a spiral vane thread of suitable dimensions cut in the outer surface of the blocks, which prevented the formation of stream-lines along one side of the tube, and secured uniformity of temperature throughout the cross-section of the outflow tube. The high conductivity of the iron also assisted in securing the same result.

A precisely analogous device for averaging the outlet temperature was applied in the water calorimeter. The bulb of the thermometer was fitted with a copper sleeve of high conductivity, on the outside of which a rubber spiral was wound to fill the outflow tube as closely as possible. The error of it was found to be much more important in the case of water than in that of mercury. The reason of this is that the thermal conductivity of water being about 25 times less than that of mercury the accurate averaging of the outlet temperature is more dependent on the uniformity of the spiral circulation and the complete elimination of geometrical stream-lines.

In order to obtain a perfect fit for the sleeves with their spiral screws it was necessary that the bore of the outflow tube should be as nearly uniform as possible and accurately straight. It was most essential that there should be no contribution at the points of junction E and F with the vacuum-jackets, and that the external portions of the tubes AE, FD should not be of smaller bore than the portion inside the vacuum-jackets, though it would not matter much if they were a little larger.

(4) Correction for Variation of the Temperature Gradient in the Fluid-Pipe. The elementary theory of the elimination of the heat loss in the steady-flow method of calorimetry assumes that, if the electric current and the flow of liquid be simultaneously varied in such a manner as to keep the rise of temperature the same, the heat loss by radiation, etc., will remain constant. The experimental results of Callendar and Barnes show that this condition is very closely satisfied in the method, and they calculated all the results of the investigation on this assumption. It was noticed, however, that there were small systematic divergences in the experimental verification for the small flows which, though amounting only to a few parts in 10,000, received careful examination as possible indications of constant errors.

So long as the distribution of temperature throughout the apparatus is accurately the same for the same rise of temperature, whatever the flow, the heat loss must also be identical. But if there is any systematic change in the temperature distribution with change of flow, then there must be a corresponding systematic difference in the heat loss, which will lead to constant errors in the calculation if no account is taken of it.

The possible sources of error of this type in the heat by conduction along the outflow pipe. When the flow is large, the heated liquid passing along the tube will keep it nearly at a uniform temperature, so that the gradient in the outflow tube will be small and the conduction loss corresponding minute. As the flow is diminished, supposing the temperature of the outflow to remain the same, the gradient in the outflow tube must increase in proportion to the reciprocal of the flow, so the radiation loss remains nearly the same. The conduction loss will vary directly with the gradient, or inversely as the flow, for a given rise of temperature.

A small error of this kind, due to conducting into a calorimeter, owing to the large masses of water in the flow tube, the small ratio of the flow, and the relatively high thermal conductivity of the liquid. It was practically eliminated by the greater part of the outflow tube from the end of the vacuum-jacket with parallel, leaving only a small passage for the outflow of memory. This made the conduction loss very small, and nearly independent of the flow.

(4) VARIATION OF THE SPECIFIC HEAT OF MERCURY WITH TEMPERATURE. The values of the specific heat of mercury in terms of the thermal unit at 15° and 16°, was calculated from the experimental data of the Congress in 1900.

The experimental results lead to the expression

\[ \text{S}_{1} = -0.0674 \times 10^{-9} + 0.00385 \times 10^{-9} \text{ or } \text{S}_{2} = -0.0003214 + 0.00001575, \]

whence \[ \text{S}_{0} = 0.003158. \]

This gives for the temperature coefficient of any temperature the expression

\[ \frac{d}{(\text{S}_{0})} = -0.0003214 + 0.00001575, \]

and for the average change per degree a value of \[ -0.0000019. \]

The data obtained in the experiments summarised in Table 1, p. 35.

§ (8) SPECIFIC HEAT OF AMMONIUM.-Professor R. H. Griffith determined the specific heat of aniline over the range 17° to 70° C., by means of an apparatus similar to that used.
to that shown in Figs. 5 and 6 of the article "Heat, Mechanical Equivalent of."

For experimental work in calorimetry oiline has various points in its favour. It has a low vapour pressure at ordinary temperatures, is a good electrical insulator, and has a low heat capacity.

On exposure to light it becomes discoloured, but no information is available to show whether this affects the thermal capacity.

For the variation of the specific heat with temperature Griffiths obtained the following equation:

\[ S_i = 0.5150 + (t - 20) \times 0.0004 + (t - 20)^2 \times 0.00002. \]

The agreement between this formula and the experimental results will be seen from the table below:

**Table I**

**Table III**

For the variation of the specific heat of oils over a wide range of temperature the apparatus shown below (Fig. 2) was employed by the writer.

![Fig. 2](image-url)

At room temperatures the oils were exceedingly viscous, and consequently it was necessary to employ somewhat unusual methods of ensuring that the contents were well mixed. The heating coils were arranged in the form of two flat paddles so that they were in continuous rotation through the oil; suitably disposed baffles further assisted the mixing of the contents of the calorimeter. It was necessary to lead the current in and out of the calorimeter by means of two annular troughs of mercury into which contact bars from the heating coil dipped.

§ (7) Specific Heat of Liquids Used for Refrigerators. Osborn has developed an apparatus suitable for the determination of specific heats and latent heats of the liquids commonly employed in refrigeration work, such as ammonia, \( \text{CO}_2 \), \( \text{SO}_2 \), methyl-chloride, and ethyl-chloride. Such determinations present greater experimental difficulties than are met with in work on liquids at ordinary pressure, since these materials have a vapour pressure varying from 1 to 70 atmospheres at the temperatures at which the thermal properties are of importance in engineering work. Consequently, in the design of apparatus for experiments of this character great attention has to be paid to details of construction.

(i) The Calorimeter. Briefly the arrange-
CALORIMETRY, ELECTRICAL METHODS OF

The material to be investigated is enclosed in a calorimeter with thick metallic walls of known thermal capacity (Fig. 3). Heat is applied electrically and the jacket is maintained at the same temperature by the usual subatmospheric arrangement.

An air space between the polished nickel surfaces of calorimeter and jacket furnishes thermal insulation. Two tubes extend from the top of the calorimeter through the jacket and liquid to the outside air, terminating in valves. One of these tubes is intended for connection to pressure-indicating apparatus and the other for the introduction and removal of the material to be investigated.

Care was taken to avoid having heavy metal connections near the air space and by suitably

**Heating Cell**

**Copper Envelopes**

**Coating Ring**

Distributing these connections which are necessary over the calorimeter surface, the part of the thermal leakage due to heat conduction was considerably diminished. Thermocouples indicate relative surface temperatures of the jacket calorimeter, 10 junctions being distributed upon each surface. This permits of central control over the thermal leakage and the correction for such leakage as cannot be avoided.

Thermocouples placed upon the connecting tubes indicate the temperature of these tubes at several points relative to a point on the jacket and in this way the temperature of the vapour expelled during vaporisation experiments could be found.

The inside of the central tube in the calorimeter is accessible at the bottom for the introduction of the heating coil and thermometer. Upon the outside of this tube are fastened 12 radial vanes of tin-iron about 0.3 mm. thick, extending to within about 1 mm. of the surrounding cylindrical wall. These vanes are for the purpose of promoting the diffusion of heat within the annular space containing the material under investigation. The vanes extend just above the top of the central tube. At this place are two flat circular baffles plates, separated about 2 mm. by three small steel studs. The lower plate is united to the tops of the radial vanes with ties. In the central hole in the lower plate and several inches in the upper one between centre and outside runs through a tortuous passage for vapour coming from below. These two plates are intended to intercept any large drops of liquid which might be thrown up by vigorous boiling, should it occur, and also act as a thermal shield for the top of the calorimeter.

A second set of four baffle plates of spherical content separated by about 2 mm. are attached to the inside surface of the central part of the calorimeter top. Each plate has a central hole and four slots at the edge so as to avoid trapping gas or liquid, but these passages are so sized and spaced that the main path through the plates is very tortuous, so as to make difficult the passage of liquid particles from below in a current of vapour being withdrawn through the outlet in the top. The entire inner surfaces of the steel shell and of the various plates within were all tinned, using pure block tin.

(ii.) Method of Experiment.—Two distinct methods of experiment were employed. In the first method the heat, added to a fixed amount of the substance under test contained in the calorimeter under saturation conditions, together with the resulting change in temperature, are measured. By using data for the specific volumes of the two phases and the latent heat of vaporisation, the heat lost in the vaporisation of the liquid is estimated and can be allowed for; thus the specific heat of the liquid when kept saturated is found.

In the second method the calorimeter is kept full of liquid at a constant pressure. The heat, added to the variable amount in the calorimeter, and the resulting change in temperature are measured. A correction for the heat withdrawn in the expelled liquid is determined by special experiments. By use of the data for variation with pressure of the latent heat of the liquid, obtained from separate measurements, made with the same apparatus and material, the corrections for pressure variation are applied, and thus a second determination of the specific heat of the saturated liquid is obtained.

As a final result, the specific heat, $c$, in joules per gram per degree centigrade, of liquid ammone, kept saturated, at the temperature $\theta$, is given in the range $-45^\circ$ to $+45^\circ$ C. by the equation

$$c = 3.1305 - 0.00037\theta + 10.842 \frac{1}{\sqrt{133 - \theta}}$$

The two curves in Fig. 4 show the results graphically.
S) SPECIFIC HEATS OF SOLIDS BY ELECTRICAL METHODS.—Very little work has been done on the determination of the specific heat heats of the metals aluminium, tin, copper, cadmium, zinc, lead, and silver over the range -10° to +100° C.

- Cadmium

- Copper

Dr. Ebor Griffiths studied \( \circ \) the specific heat of substances by the electrical method. Due to the nature of the metals, the method, of course, itself admirably to the determination of specific heats of good thermal conductors, with poor conductors special devices must be used to ensure uniformity of temperature throughout the material under test.

**GACDE.**—Gacde \( 1 \) appears to have been first to measure specific heats in this way. In his experiments the specimens and their own calorimeters. These were fitted to a cylindrical form and a deep core bored out. Into this was thrust a core, wound with a properly in- 

culated heater of constantan ribbon and a fine copper wire. Care was taken to fill the core and this calomel was suspended in a vessel and heated through an accurately measured temperature interval of about 15° measured quantity of energy supplied.

**Few particulars of the investigation have been published, and the data obtained have been published, and the data obtained are summarised in Table IV.**

**METALS.**—Professor E. H. Griffiths studied the specific heat of the metals aluminium, tin, copper, cadmium, zinc, lead, and silver over the range -10° to +100° C.

**Zeitschr., 1922, iv.**

(I.) Temperatures 0°-100° C.—The apparatus employed for determinations in the range 0° to 100° C. is shown in Fig. 5.

Two similar blocks of the metal under test were suspended in two brass enclosures immersed in a constant temperature bath. In the central hole of each block was a heating coil whilst the coaxial holes contained resistance thermometers connected differentially.

The third hole was used for the purpose of cooling the block below the surrounding temperature by the insertion of a thin-walled tube containing water and connected to a water pump.

In the experiments one of the blocks was heated through a range from one degree below the temperature of the enclosure to one degree above the temperature of the enclosure by a measured supply of electrical energy.

This temperature interval was measured on a resistance bridge in the usual manner. Since the two resistance thermometers were adjusted to close equality and made of the same sample of wire, the balance point on the bridge wire was practically at the centre of the wire at all temperatures when the blocks were in temperature equilibrium with the enclosure. Hence no auxiliary coils were required in the Wheatstone’s bridge circuit beyond the equal ratio arms.

The energy supplied to the heating coils was measured by balancing the potential difference at its ends against the E.M.F. of a series of cadmium cells in series, the current through the coil being adjusted until balance was obtained.

The resistance of the heating coil was determined for the particular value of the current passing.

(II.) Low Temperatures.—The experiments were continued at low temperatures but with a modified form of apparatus shown in Fig. 6, as it was very difficult to obtain any constant temperature baths in the region from −20° to −100° C.

In this apparatus a constant temperature enclosure was obtained by the use of a thick-walled copper box surrounded by a coil of tubing through which cooled air was circulated. The Joule-Thomson effect of cooling was utilized in a different manner. Air was compressed to a pressure of 2000 to 3000 lb. per sq. in. and then entered into the interchanger by the pipe A, Fig. 6. This interchanger B-B was constructed of very solid drawn copper tubing 1/4 in. bared in the form of flat spirals. Successive layers of the coil were separated by strips of cardboard and the entire coil packed
around with heat-insulating material. From the interchanger coils the air was carried to the valve C, by means of which an observer controlled the flow, excess of air being discharged at the safety-valve on the compressor. After expansion the air circulatated through the coil of lead tubing D, and then back over the surface of the interchanger coils. On the exterior surface of the thick-walled copper enclosure E was wound a layer of insulated copper wire, which served as a resistance thermometer. Variations in the temperature of the walls of the enclosure were rendered visible by the movements of a galvanometer spot. By controlling the flow of air the oscillations of the spot could be kept within narrow limits and, under normal conditions, the oscillations did not exceed a hundredth of a degree in amplitude.

The interior of the wooden vessel M was packed with slag wool, the passage for the withdrawal of the copper enclosure being kept clear by a cylindrical tube of cardboard N. The space between the top of the enclosure and the outer lid was filled by wrapping felt matting around the glass tubes and leads.

The block of metal C was suspended within the enclosure by a single glass tube H. The central hole contained the heating coil O, of manganin wire wound on a mica rack and immersed in a light paraffin, usually petrol. The heating coil was fixed to a short tapering core of copper K, which closed the central hole. The resistance of the coil was about 20 ohms. A platinum thermometer was inserted in the cylindrical hole T, the annular gap between the stem and the walls being closed by a packing of asbestos thread. The differential arrangement employed in the previous experiments was abandoned as it would have required too long a time to obtain the equilibrium conditions.

(b.) Method of Experiment.—In these experiments the practice was to heat the material through a small temperature interval from below the surroundings in an approximately equal interval above, and observe the rate of rise during this period. The method of experiment was such that a direct determination of the temperature of the enclosure was not required. An experiment was conducted as follows:

The temperature of the enclosure was lowered progressively by utilizing the full supply from the compressor and controlling the flow so as to produce a steady pressure drop through the valve of 120 to 150 atmospheres.

The temperature of the block would fall at a steady rate by radiation and convection to the enclosure and, when its temperature had nearly reached the desired point the coil air circulation around the enclosure was stopped.

Its temperature would then rise rapidly by conduction from without and soon pass that of the block which, in consequence of the slow transmission of heat by radiation and convection, would lag behind that of the walls. The temperature of the enclosure walls would then be maintained steady at about three degrees higher than that of the metal block.

Some time had to elapse before the conditions were sufficiently settled to justify the commencement of an experiment.

The first group of readings consisted of observations of the rate of rise of temperature of the block by radiation, etc., the transient of the temperature being observed across successive equal intervals (of about \( \frac{1}{60} \)th of a degree), the time between successive transits being of the order of 60 seconds.

The electrical supply was then switched on, and, after allowing a little time for the setting up of a steady gradient, transits every fifth of a degree were taken.

When the temperature had risen two or three degrees above the surroundings the electrical supply was switched off and observations of temperature and time continued.

The temperature would then fall steadily under the influence of radiation, etc., the rate of cooling being observed in precisely the same manner as the rate of rise of temperature before the electrical supply was switched on.

If \( s \) is the rate of rise or fall due to radiation for 1°C difference in temperature between the block and the surroundings, then assuming Newton's law to be valid for the loss or gain by radiation (an assumption which was fully justified by the experimental results), we have the expression

\[
\frac{\Delta T}{\Delta t} = s(\theta - \theta_0)
\]

for the rate of rise or fall under the influence of "radiation" alone. Hence, plotting \( \frac{\Delta T}{\Delta t} \) against \( \theta \), the straight line joining the two groups will cut the temperature axis at \( \theta = \theta_0 \) which determines the temperature of the surroundings.

For the rate of rise under the combined effect of the electrical supply and radiation we have the equation

\[
\frac{\Delta T}{\Delta t} = \phi R + s(\theta - \theta_0),
\]

where \( \phi R \) is the electrical supply per second in thermal units, MS the thermal capacity of the block including that of the resistance coil, etc.

Plotting the observed rates of rise on the same scale as the "radiation" observations, it is obvious that the straight line thus obtained should be parallel to the line joining the two groups of "radiation" observations, since the tangent of the angle made with the \( \theta \) axis is equal to \( s \). For \( \theta = \theta_0 \) the "radiation" term
KLEOTRICIAL METHODS OF

vanishes, hence, if \( \frac{\partial \theta}{\partial t} \) denotes the value of the ordinate at this point, then

\[
\frac{\partial \theta}{\partial t} = \frac{E^2}{c_t \cdot \text{RMS}}
\]

from which \( S \) can be obtained. The results obtained are summarised in Table V and shown graphically in Fig. 7, where \( T \) is the absolute
temperature and \( C_0 \) is the atomic heat, i.e. specific heat multiplied by the atomic weight.

§ (11) **NORST AND LINDHOLM**.—The observers made a series of point determinations at very low temperatures, using a calorimeter developed by Eucken. A piece of metal of suitable size was shaped into a hollow cylinder and a loosely fitting cork made for the same. On the core was wrapped a platinum wire, properly insulated, to serve as a resistance thermometer and also as electric heater. The core was placed in the cylinder and paraffin poured into the enclosure to improve the thermal contact (see Fig. 8). The whole was suspended in vacuo, and the specific heat over small temperature intervals determined from measurements of energy supplied electrically and of the temperature rise resulting therefrom. Norst and Lindholm applied the same method to poor heat conductors. For such materials the design of calorimeter is shown in Fig. 9. The wire was wound on a silver tube projecting into a silver vessel, the high conductivity of the silver assisting the equalisation of the temperature through the mass. Some of the data for these metals obtained by Norst are given in Table VI.

§ (12) **COPPER**.—Harper 3 studied (i) the specific heat of copper over the range 15° to 50° C. The specimen was in the form of copper wire, which also served as its own thermometer and heater. The wire was 50 metres in length and 2-6 mm. in diameter; it was compactly coiled in a number of flat spirals separated by copper plates. The coil was suspended in vacuo, and heated with a measured quantity of energy supplied electrically, the resulting temperature rise being measured by the change of resistance.

---

RESULTS OF 27 DETERMINATIONS BETWEEN 15° AND 60° ARE REPRESENTED BY THE EQUATION

\[ S = 0.0917 + 0.000011(t - 35) \text{ calories} \text{ per gram degree} \]

4.182 joules is taken as equal to one 25° calorie.

(ii.) Comparison of Data by Various Observers.—Harper \(^1\) has tabulated the data given by various observers for the specific heat of copper. In order to compare the results at one definite temperature the coefficient 0.000044 has been used in reducing results obtained at different temperatures.

It will be observed from a comparison of the data given in Table VIII (p. 42) and shown graphically in Fig. 10 that there is substantial agreement between the results of observers using the electrical method both as regards the absolute value of the specific heat and its temperature coefficient. It is very improbable that there is any systematic error common to all data, the three methods differ radically in detail.

\(^{(13)}\) SORPTION OF GAS BY ELECTRICAL METHODS.—The method of electrical heating for the determination of the specific heat of gases at different temperatures has been developed by Callendar and his associates.

Gases present greater practical difficulties being assumed as valid for values of \( t \) from 0° to 100°.

</table>

The unities in terms of which the above results are expressed are not all the same, but the differences need not be taken into account in making comparisons. Hence in every case the difference between the unit employed and the 10° calories or the 20° calorie (which differ from each other by about one part in a thousand) is less than the probable experimental error.

Calorimeter.—The continuous flow method was used in the determination of the specific heat of air and carbon dioxide at atmospheric pressure at 20°C and 100°C. In these experiments a steady stream of gas was passed through a jacketed tube (the calorimeter proper), in which it was heated by a current of electricity passing through a platinum coil of 1 ohm resistance, the rise in temperature being measured by two 12-ohm platinum thermometers used differentially.

The calorimeter was represented diagrammatically in Fig. 11. The heating coil and platinum thermometers being situated in the tube AB, which is jacketed by the tube J. The tube FG formed the heater in which the gas attained the desired temperature, and being double-walled could be steam-heated or water-cooled. This tube was packed with tightly fitting discs of copper gauze. The gas under test entered at m, was heated up to the required temperature and entered the space round the calorimeter proper. It next passed through the tube n, into the calorimeter, and finally emerged by the tube p.

The general arrangement of the apparatus will be understood from Fig. 12.

---

(ii) Theory of Method.—If \( Q \) is the electric current, \( \Delta T \) the potential difference between the ends of the heating coil, \( \Delta T \) the rise in temperature of the gas, \( \frac{d}{dt} \) the rate of flow of the gas in grammes per second, \( J \) the mechanical equivalent of heat, and \( S \) the specific heat of the gas at constant pressure, the elementary theory of the experiment gives

\[
Q \cdot \Delta T = 4.1 \Delta T \quad \text{(14)}
\]

where \( \Delta T \) is a term representing the heat loss by radiation, etc.

A similar experiment with a rate of flow about half the above value, and with the electric current adjusted so that the rise in temperature was about the same as before, gave a second equation, so that it could be eliminated and \( S \) determined.

The largest currents of gas through the apparatus were of the order of 0.5 litre per second. The rate of flow was kept constant by an automatic pressure regulator. It was measured by passing the gas through 16 fine metal tubes arranged in parallel, and observing the pressure difference between their ends, the mean pressure, and the temperature. The expression giving the rate of flow in terms of these quantities was found by a series of experiments in which the gas was pumped into a reservoir of about 50 litre capacity, and then allowed to discharge through the apparatus. By means of a special device, the times taken for certain quantities of gas to pass through the apparatus were recorded automatically while the gas was actually flowing, so that the initial fluctuations were avoided.

The value of the electric current was obtained by measuring the potential difference set up at the ends of a standard resistance coil in terms of platinum coils. The heating effects of the leads of the heating coil were determined by experiments made under the exact conditions of the main experiments.

The rise in temperature in the main experiment was about 6° C., and it was measured to 0.001° C. Thus the specific heats were measured practically at single temperatures instead of over large ranges.

The validity of assuming the heat loss for a given rise in temperature to be independent of the rate of flow of the gas was tested by experiment. The matter was also examined from a theoretical standpoint, and corrections were calculated and applied where the assumptions made in the elementary theory were such as to lead to errors of more than about one part in 10,000. The corrections were small, only amounting to one or two parts in 1000.

Full details of various other precautions are given in the original paper, and the mean of a large number of observations gave the following:

Air
-2417 cal. per gram degree at 80° C.
-26201 cal. per gram degree at 100° C.

Carbon Disoxide
0-2022 cal. per gram degree at 20° C.
0-22121 cal. per gram degree at 100° C.

The values of the specific heats obtained are greater by about 2 per cent than the corresponding values found by Regnault and by later investigators who have employed methods similar in principle to that of Regnault, but it has now been established that Regnault’s method gives values which are low by about this amount.

§ (14) SPECIFIC HEAT OF STEAM.—Brinkworth \(^2\) developed the same method for the determination of the specific heat of steam at atmospheric pressure between 101° C. and 115° C.

(i) Outline of the Method.—Steam is generated in a boiler and then led to one limb of a U-tube pressure regulator. The pressure of the steam forces the mercury down in this limb of the U-tube and up in the other limb in which the adjustment of the supply of gas to the large ring burner, used for heating the water in the boiler, is made.

After passing the required amount of steam, now maintained at a constant pressure, in led between the walls of the jacket surrounding the calorimeter proper, through a separator and a throttle into the space enclosed by the double-walled jacket, whence it passes down the calorimeter flow-tube to a condenser. During the passage of the steam through the flow-tube it is heated by means of an electric current passing through a platinum heating coil, and its temperature is measured on a platinum resistance thermometer. Another thermometer measurement is made when the supply of electrical energy is cut off, and the difference between these two temperatures gives the rise in temperature of the steam.

(ii) Calorimetric Arrangements (Fig. 13).—The calorimeter proper consisted of a glass tube \( Y \), about 50 cm. long, in which the heating coil \( C \) and the thermometer \( N \) were fixed. This tube was jacketed by another glass tube \( S \), which enclosed the length occupied by the heating coil and thermometer.

The calorimeter flow-tube and its surrounding glass sheath were carried on a split rubber cork and were fixed in a steam-tight joint into a space enclosed by a double-walled brass jacket. The lower part

---

CALORIMETRY, ELECTRICAL METHODS OF

of this jacket communicates with a double-walled side tube and the steam entering at E passes between the jacket walls to F, which communicates with the steam separator G. It then enters the inner portion of the side tube through the throttle T. This tube is tightly packed with glass discs; thence the steam passes up the tube S into the top of the flow-tube at P, and descending past the heating coil C and the thermometer N flows away into the condenser at L.

On its passage through the tightly packed glass discs in the side-heating tube the steam was heated up to the temperature of the jacket.

In Fig. 13, which represents diagrammatically the arrangement thus described, it will be noticed that the cylindrical space inside the double walls of the main jacket is divided into two compartments by a disc K. This disc of brass was soldered to the inner jacket tube about 5 cm. from the upper end. Its function is to prevent the steam in the tube S from impinging on the rubber cork closing the upper end of the tube, and thus being cooled. Any slight cooling due to the steam striking the lower split cork is of no importance, since the steam would be warmed again during its passage up between the flow tubes and the surrounding jacket. The whole of the jacket, the separator, and the connecting tubes were heavily lagged with felt. A novel feature of the apparatus is the "spiral" method of mixing the steam, in which use is made of a number of circular discs punched to fit the thermometer tube and then cut along a diameter, bent, and soldered together to form a continuous spiral round the thermometer (see Fig. 14). This method of mixing is found to be a great improvement on the glass method previously employed.

The usual equation for the continuous flow method is

\[ EC = SQ\theta + h\theta \]

where EC is the electrical energy supplied, S the required specific heat if expressed in joules per gram C, Q the rate of flow of the steam, \( d\theta \) the rise of temperature of the steam, and \( h\theta \) in a term representing the heat loss. If this loss is independent of the flow, then a linear relationship exists between the values of \( EC/Q\theta \) and \( 1/Q\theta \). This is found not to be strictly the case, and another term depending on the flow is inserted in the fundamental equation which thereby becomes:

\[ EC = SQ\theta + (k + h)Q\theta \]

By the employment of three rates of flow, adjusting \( k \) in each case so that \( d\theta \) remains the same, \( h \) and \( k \) can be eliminated and \( S \) measured.

The value obtained for the specific heat was 0.4886 cal per gram degree at 101.4° C. and 760 mm. pressure; then, assuming a linear variation with temperature as experimentally determined, this corresponds to a value 0.4878 at 100°, both expressed in terms of the calorie at 20° C.

(iii) Effect of Impurities in the Steam.-Steam in the immediate neighbourhood of the saturation point is liable to carry small particles of water in suspension, which cannot be evaporated completely by a moderate degree of agitation if any impurities, such as salts in solution, are present. Since 1 mg. of water requires more than half a caloric to evaporate it, and the heat required to raise the temperature of 1 gram of steam 10° C. is only 0.5 calories, it is necessary that the initial steam should not contain more than 1 in 100,000 of water if the specific heat is to be found correct to 1 in 1000 over a range of 10° C.

The rise of the boiling-point \( \theta \) produced by a gram-molecule of salt per gram of water is approximately 1000° C. The proportion of suspended water remaining unevaporated at any degree of superheat \( \theta' \) will be 1000(\( \theta' - \theta \))/\( \theta' \). The quantity evaporated in heating the steam from \( \theta' \) to \( \theta' \) will be 1000(\( \theta' - \theta \))/\( \theta' \). This will produce an apparent increase of the mean specific heat of the steam over the range \( \theta' - \theta \) equivalent to 1000Lx(\( \theta' - \theta \))/\( \theta' \), where \( L \) is the latent heat of evaporation. It was found that this extremely simple and convenient reduction formula fitted the results obtained over different ranges of temperature with extraordinary precision, and reconciled apparent discrepancies which had previously been attributed to errors of observation.

§ (15) Determination of the Specific Heat of Air and other Gases at Room and Low Temperatures by the Continuous Flow Electrical Method.—Schoel and House have determined the specific heat of air and other gases at +20°, −78°, and −183° by the continuous flow method. The air was directed in a steady stream through a pipe in which it received a known amount of heat by means of a heating coil.

Fig. 15 shows the glass calorimeter in the form in which Schoel and House used it. The

CALORIMETRY, ELECTRICAL METHODS OF

gas, which is brought to a steady temperature, enters the calorimeter from below and flows through a spiral, then through two glass jackets C and D, and finally reaches the inner tube A which contains the heating coil. The temperatures of the in- and outflowing gases are determined by the resistance thermometers \( P_1 \) and \( P_2 \). The whole is surrounded by a vacuum and a glass jacket silvered inside and is contained in a bath at constant temperature. As the air at first flows through the jackets C and D before it reaches the real calorimeter, it absorbs the greater part of the heat given off to the inner vacuum according to the principle of counter current and thus assists the insulating action of the jacket. This greatly reduces the loss of heat, but does not entirely prevent it. The temperature of the outflowing gas is measured in the transverse section M.

The heating coil is shown in Fig. 10 and consists of constantan wire K and is wound in two sections on a glass pipe. In order to distribute the heat equally the wire is wound together and wound around the fine copper wire \( \Omega \) as far as possible. The wire coils supported above and below by perforated ivory strips \( E_1 \) and \( E_2 \). In order to mix the gas thoroughly, the packing of copper wire gauze \( \Omega_2 \) is introduced above the rod, which in its turn is fastened with an ivory strip \( E_3 \). The wires which conduct the current to the heating coil are led up through the inner glass tube and connected above \( E_3 \) with the wires to the heating coil and apparatus for mixing ammonia into a number grout in the inner pipe A.

When working at room temperature, the calorimeter was placed in a large water bath well stirred. At low temperature, on the other hand, it was placed in a vacuum vessel which contained a mixture of \( CO_2 \) and alcohol or liquid oxygen. In each case the gas, before entering the calorimeter, passed through a pipe which was contained in the same bath as the calorimeter.

The same investigator, when using helium and some other rare gases in low temperature, modified the apparatus so as to employ a closed circuit.

The results they obtained are summarized in Table IX. They also calculated the corresponding values for the ideal gas at \( \text{T} = 90^\circ \).

CALORIMETRY, ELECTRICAL METHODS OF

these results are inserted for comparison alongside the others.

The values at constant volume are obtained from the experimental numbers at constant pressure by means of the expressions deduced by a combination of the ordinary thermodynamic equations with D. Berthelot's equation of state.

§ (16) VARIATION OF THE SPECIFIC HEAT OF AIR WITH PRESSURE OVER THE RANGE 1 TO 1200 ATMOSPHERES.

In 1914 Holborn and Jacob² made a new series of measurements of the specific heat of air high pressure by an electrical method. The calorimeter employed is shown in Fig. 17. The castings used in this construction were made of nickel steel of high tensile strength. The air enters the calorimeter at the bottom through a small spherical piece $c_1$ and leaves at the top through a similar arrangement $c_2$. Between these two points there is a nickel steel pipe $c_3$ with semicircular ends $c_3$ and $c_4$ into which the two pipes $c_3$ and $c_4$ lead for the entrance and exit of the current of air. Connections between the various pipes are made by flanges fitted with packing rings.

A heating coil $q_1$ through which the air flows is enclosed within the pipe $c_4$, from here the air passed through the annular spaces $l_1$ and $l_2$, its direction being changed twice before it leaves the calorimeter. The spaces $l_1$ and $l_2$ are enclosed within three nickel walls. The direction of the air current is indicated by the arrows in the figure.

The outer space of the calorimeter is also divided into two cylinders $c_5$ and $c_6$, through which air from the small turbine $r$ is driven in the direction of the arrows. The oil can be heated when desired by means of the resistance coil $q_3$. $d$ is a steam jacket surrounding the calorimeter and the exit pipe, leaving the entrance pipe quite free. This latter pipe is protected against heat loss by a wrapping of twisted silk and from the action of the incoming air by a glass pipe inserted in it. The heater $q_1$ consists of a group of 60 split nickel tubes about 4 mm. inner diameter and 4.5 outer diameter. These are fastened to two porcelain plates and are held together, one behind the other, by clips. The air passes through and around the tubes; current is supplied to this heater by wires insulated with glass.
CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

The results at a temperature of 0°C are represented by the empirical formula:

\[ 10^\circ C = 2413 + 2.86p + 0.00005p^2 - 0.000001p^3, \]

where \( p \) is the pressure in atmospheres.

The value 0.2413 obtained for the specific heat at 0°C and one atmosphere pressure agrees very satisfactorily with those obtained by Swan (2.413 at 207) and School and Hense (2.444). It of course differs from Regnault's value, which is now known to be low.

The following table gives the values obtained for the specific heat at a temperature of 0°C, and for various pressures measured in kilogram per cm.:

For comparison purposes the results of Jähncke and Neill agree within the errors of the experiment with the values calculated from the relations 0.2413 for Neill and 0.2413 for Jähncke. These were obtained from Linde's formula:

\[ C_p = C_v \left(1 - \frac{\alpha}{v} \right), \]

where \( C_v \) is the specific heat at pressure 0 and \( \alpha \) the adiabatic coefficient. The volumes are obtained by subtracting the specific heat at pressure 0 from the specific heat at a given pressure.

E. G. THOMASSON

CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

§ 1. The Method.—In this class of calorimetric apparatus the quantity of heat to be measured is determined in terms of any one of the following: (i) The mass of ice melted; (ii) steam condensed; (iii) liquid hydrogen or oxygen vaporized.

Such measurements do not require an accurate measurement of small temperature changes of the calorimetric fluid, and taking into consideration the state of thermometry half a century ago, this fact was unquestionably of real advantage. Further, the temperature of the surrounding atmosphere can have but little effect upon the indications of the calorimeter since the initial and final temperatures are the same. In recent years calorimetric thermometers have been so highly developed that the measurement of small temperature changes presents no serious difficulty, and the technique of temperature control of the jacket has been greatly facilitated by the use of electrical heating, so that the inherent difficulties associated with the method of calorimetry now under consideration more than counterbalance the advantages it offers; consequently, it is very little used at the present day.

The Bunsen ice calorimeter and the steam calorimeter are classical examples of this method of calorimetry.

Bunsen has applied the same principle to specific heat determinations at very low temperatures, and obtained data concerning the mean specific heat of materials between liquid hydrogen and liquid nitrogen temperatures.

§ 2. Bunsen's Ice Calorimeter.—In this instrument the heat given out by a body in cooling from some higher temperature to 0°C is obtained by observing the contraction which takes place in the change from ice to water produced by the heat given by the body.

The observed volume change is converted into calories by assuming a value for the constant of the ice calorimeter, i.e. the mass of mercury drawn into the instrument by the addition of one mean calorie of heat.

Numerous determinations of this constant have been made and the values are summarized in Table 1.

It might be remarked that many of the above values are based on observations of the latent heat imparted to the calorimeter by a small quantity of water contained in a vacuum whose thermal capacity was comparable with that of the contained water. Since in the majority of cases no attempt has been made to vary the conditions and thus effect systematic errors, all the values are not entitled to the same weight. For example, the figure given by Bunsen is the mean of two experiments represented...
under precisely similar conditions: the glass envelope
weighted 0.2 gm., contained 0.2 gm. of water, and a
platinum sinker (weight 0.5 gm.) was also attached.

Bunsen determined the quantity of water from 0-6
gm. to 2 gm., and consequently his determination
is entitled to greater weight than the others.

Grigil's value was obtained by supplying a known
quantity of heat measured as electrical energy. The
heat supplied by a manganese coil wound on a
iron wire which fitted the interior tube of the
calorimeter (see Fig. 2), and the results are based
on the electrical units of E.M.F. and resistance.

The conditions were varied. Thus the rate of
energy supply in the fastest experiments was more
than seven times that in the slowest, and the probable
error by the method of least squares was less than
0-1 per cent.

Bunsen employed his ice calorimeter to
determine the latent of fusion of ice as follows:

Known weights of water at a known boiling
temperature were introduced into the inner
tube of the calorimeter and the contractions
observed.

In a separate experiment a known weight of
ice at 0° C. was contained in a bulb, the
rest of the space being filled with mercury.

The ice was melted to water, the temperature
being maintained at 0° C. Mercury was drawn
into the bulbs to occupy the space left by the
ice in melting, and from the additional weight of
mercury the contraction was obtained.

He found that the melting of 1 gm. of ice
caused a contraction of 0.0087 cc.

From the results of the two sets of experi-
ments he calculated the latent heat of water
to be 80-025 calories, which is 0-3 per cent
higher than the value obtained in recent
direct determinations.

The method is not a good one for deter-
mining the latent heat of water, since the con-
talmes depend on the difference of the
volumes of ice and water.

§ (3) BUNSEN'S CALORIMETER AND
MODIFICATIONS. (r.) Description. — A
vertical test-tube A is lined into a large
bulb B, as shown in Fig. 1. The bulb
is furnished with a glass stem C, which
stands in an iron collar D. This stem
is provided with a blue-bearred mercury, which
fills the bulb to the level β. The remains
of the bulb above β is filled with pure
water. A calibrated narrow glass tu-
neled with a millimetre scale, is
into a cork with fine scaling-wax, and
passed through the mercury in the soil
and made fast in the mouth of the tube
so that it becomes filled with mercury;
by adjusting the cork in the mouth of
tube OD the extremity of the mercury in
the scale tube S can be placed at
convenient point. By means of this
described in most text-books on
physics, a mark of ice is formed above
lower part of the tube A.
CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

that the density of ice is not a constant quantity.

The experimental evidence on this point is briefly summarised below:

Nicholls reviews the work of previous investigators on the density of ice and describes his experiments. He concludes that the density of ice mantles, determined by weighing in petroleum, is 0.91615 ± 0.00005. This result agrees with the mean value derived from different methods by Pflüger and Geissler, Kopff and Hensen (for a similar variety of ice) in four pieces of decimals.

His experiments on the causes of the variations in density of artificial ice were not completed. The method was to freeze the ice mantle around the inner tube of a calorimeter by pouring in a mixture of CO₂ and ether. The unfrozen water was shaken out as completely as possible, and the adhering water frozen, the remaining space being then completely filled with mercury. The weight of the mercury, together with that of the ice, gave the data for the computation of the density of the ice mantle.

Although the results were consistent among themselves the absolute value was subsequently found to agree with that of the mantle obtained by means of alcohol at -5° to -10° as recorded in the manner devised by Hensen. The measurements appeared to indicate that the mantle formed by the ice of alcohol at -5° to -10° was less dense than those formed by means of O₂ and other at -70° by at least 1 part in 1000, and further that one of the latter mantles decomposed in density by nearly this amount after standing 24 hours in an ice bath.

The use of CO₂ and ether resulted in a very rapid formation of ice, and the mantle, when a certain size was reached, invariably became filled with a network of fine cracks.

Vincent later took up the subject, and investigated the coefficient of cubical expansion of ice. He prepared the ice by means of a freezing mixture and appears to have obtained a different density for each sample prepared. Table II summarises all his results:

<table>
<thead>
<tr>
<th>Experiment</th>
<th>Density Ice at 0°</th>
<th>Weight assigned to the Experiment</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.916350</td>
<td>3</td>
</tr>
<tr>
<td>2</td>
<td>0.91500</td>
<td>2</td>
</tr>
<tr>

<td>2</td>
</tr>
<tr>
<td>4</td>
<td>0.915640</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>0.916000</td>
<td>2</td>
</tr>
</tbody>
</table>

Weighted mean 0.9160

His values for the coefficient of expansion of the above samples are consistent, and no connection between variation in density and expansion can be traced. Vincent's mean value for the density of ice was 1 part in 5000 less than the mean of the results of Pflüger and Geissler, Kopff and Hensen.

The experiments of Ledbe in 1906 suggested one cause of the variations in density which had been observed by previous workers. Ledbe took extreme precautions to get rid of all traces of dissolved air in the water used for manufacturing the ice samples. He condensed the steam from boiling water under oil to obtain air-free water.

The results of these experiments indicated that the density of ice at 0° was not less than 0.9172, and as greater efforts were made to remove traces of gases the values obtained for the density increased. He concluded that the density of frozen ice at 0° would probably be 0.9176.

It is of interest to note that Linfoot considers that ice made from water which has been merely boiled, as in the case of the Hensen calorimeter, still contains about 1 ccm of gas per litre at atmospheric pressure.

Another possible cause of the variations in density is the tension set up in the ice block on formation and which disappear in the course of time.

§ (4) JULY'S STEAM CALORIMETER. (I.) Method.—In the steam calorimeter devised by July in 1886 the heat necessary to raise the temperature of a body from the air temperature to 100° is measured by determining the weight...
CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

of steam which must be condensed into water at 100° to supply this heat.

The instrument, especially in its differential form, has been found very useful for special purposes. But the experience of most users indicates that the condensation method is more troublesome to use than the method of mixtures for the determination of the specific heats of solids and liquids. In the hands of Joly, however, the steam calorimeter has produced data of fundamental importance concerning the specific heat of gases at constant volume.

One disadvantage of the condensation method is the fact that less than 2 milligrams becomes at once filled with saturated vapour. Condensation immediately begins on the substance and the resulting water is caught in the pan, weights being added to the other pan of the balance so as to restore equilibrium. During the process of weighing, the steam is passed through very slowly (by opening an escape tube leading from the boiler) into the calorimeter, so as to avoid disturbance of the pan.

After four or five minutes the substance has generally attained the temperature of the steam, and the condensation is completed. The pan then ceases to increase sensibly in weight, and the equilibrium of the balance is maintained permanently. A very slow

of water is deposited per calorie, and consequently it necessitates accurate weighing.

(i.) The Apparatus.—The simplest form of Joly’s apparatus consists essentially of a steam chamber of thin metal in which is suspended from the arm of a balance a small platinum pan (Fig. 3), carrying the substance under test.

Steam can be turned on to this chamber, as indicated, and escapes through a pipe at the base.

It is essential to arrange the inlet valve so that the steam can be admitted rapidly for reasons which are explained later.

(ii.) Method of Experiment.—The substance is weighed with air in the chamber and the temperature carefully noted. Steam in the meantime is got up in the boiler, and is suddenly admitted, so that the whole chamber increases of three or four milligrams per hour (due to radiation) is, however, noticed. Let \( \theta_1 \) be the temperature of the steam and \( L \) its latent heat. If \( w \) is the increase of weight the quantity of heat given out by the condensation is \( wL \), and this is expended in raising the substance and the pan from \( \theta_1 \) to \( \theta_2 \). If \( W \) be the weight of the substance, and \( s \) its specific heat, the heat acquired by the substance will be \( W(\theta_2 - \theta_1) \), and that acquired by the supporting pan will be \( k(\theta_2 - \theta_1) \), where \( k \) is the thermal capacity of the pan, that is, the quantity of heat necessary to raise the temperature 1° C. Hence we have

\[
W(\theta_2 - \theta_1) + k(\theta_2 - \theta_1) = wL.
\]

The quantity \( k \) is determined by a previous observation, and the temperature \( \theta_2 \) is found either directly, by a thermometer inserted in

![Figure 3](image-url)
the steam-chamber, or by means of Regnault's tables and a reading of the balance.

For extreme accuracy a small correction is still necessary. The weight $W$ of the substance is found in air at $\theta_2$ and the weight $w$ is found when the substance and pan are in steam at $\theta_2$. The weight of steam per cubic centimetre at 100° is little more than half that of air at ordinary temperatures; for this reason the weight $w$ is greater than the weight of vapour condensed by excess in weight of a volume $v$ of air at $\theta_2$ over the same volume of steam at $\theta_2$, where $v$ is the volume of substance and pan together. The difference of weight of a cubic centimetre of air at 16° C and a cubic centimetre of steam at 100° is -0.000330 gram, according to Regnault; hence the correction to be applied to $w$ is -0.000330$w$.

This correction being applied, the weight of water condensed is determined, but it must be remembered that the weighing is made in steam; and, if extreme accuracy be desired, it is still necessary to multiply by the factor 1-000580, in order to reduce the weighing to vacuum. The actual weight in a vacuum of the water condensed will therefore be

$$1-000580w - 0.000330w,$$

so that $w$ is determined from the equation

$$(W + \varepsilon)(\theta_2 - \theta_1) = 1-000580w - 0.000330w.$$

Reference should be made to § (6) of the article on "Latent Heat" for values of $\varepsilon$. In order to avoid the combustion of steam on the suspending wire, where it leaves the steam chamber, it passes, not through a small hole in the metal, but through a small hole placed in a plug of plaster of Paris. Without the plaster the steam condenses on the metal and forms a drop at the aperture through which the suspending wire passes, and destroys the freedom of motion of the wire and prevents accurate weighing. With the plug of plaster of Paris no such drop collects, and the weighing can be performed with accuracy. In his later experiments, Professor Joly placed a small spiral of platinum wire around the suspending wire just outside the aperture, and by passing an electric current through the spiral, sufficient heat is produced to prevent condensation on the suspending wire in the neighborhood of the aperture. Besides accuracy in weighing, a point of prime importance is the rapid introduction of the steam at the beginning of the experiment. When the steam first enters the calorimeter, partial condensation occurs by radiation to the cold air and the walls of the chamber. Some of the condensed globules may fall upon the substance and lead to an error in the value of $w$. If the steam enters slowly this error may be large, and it is therefore important to fill the chamber at once with steam. This constitutes a good supply of steam and a large delivery tube, but when the chamber is well filled with steam a very gentle afterflow suffices. If the supply be cut off, the weight of condensed vapor diminishes. This arises from the $\text{vapor}$ to the colder walls of the chamber, and on be again turned on the weight of condensed globules on the pan during the initial stages of the experiment is somewhat counterbalanced by radiation from the steam to the substance.

§ (5) The Differential steam calorimeter for the determination of Specific Heats of Gases at Constant Volume.—In the differential form of the steam calorimeter the correction for the weight of steam displaced by the pan is eliminated. In this form (Fig. 4) two similar pans hung in the steam chamber, one suspended from each arm of the balance so as to counterpoise each other. The thermal capacity of the pans can be made equal, so that the term with $k$ as a coefficient does not appear in the equation, and the radiation error will also disappear, as it will cause equal condensation on the two pans.

The chief use of the differential form is, however, its application to the calorimetry of gases; for this purpose the pans are replaced by two spherical shells of copper, one containing the gas at a known temperature and the other empty. The spheres are furnished with small pans, or "catch-water," to collect the water resulting from condensation. Greater condensation occurs on the sphere which contains the gas, and the excess gives the quantity of heat required to heat the contained mass of gas from $\theta_2$ to $\theta_1$. This determines the specific heat of the gas at constant volume.

The great advantage of the differential calorimeter is that any source of error common to the two spheres is eliminated, and the gas or other substance enclosed in one of them merely bears its own share of error and not that also of the containing sphere. Thus the effect is practically the same as if the gas were contained in a vessel of zero thermal capacity in the single steam calorimeter form.

The spheres employed by Professor Joly were of copper and about 0-7 cm. in diameter, the one containing the gas being made to stand a safe working pressure of about 30 or 40 atmospheres. If at the beginning of the experiment this space is filled with air at about 22 atmospheres at $\theta_1$ the pressure will rise to about 30 atmospheres at $\theta_2$. In one experiment the weight of air contained was 4-2854 grams. The condensation observed as due to the air was 0-16217 grams. This required a correction to compensate for the difference in weight of the spheres. The corrected value was 0-11029, the range of temperature, $\theta_2 - \theta_1$, being 84-52° C. In a series of six experiments the mean precipitation per degree centigrado was 0-018004.

The following corrections are also necessary:

(a) Correction for the thermal expansion of the vessel, and the consequent work done
CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

by the gas in expanding to this increased volume.

(b) Correction for the dilatation of the sphere under the increased pressure of the gas as the temperature rises.

(c) Correction for the thermal effect of stretching of the material of the sphere. (Wires are generally cooled by sudden extension, but the cooling of the copper in this case is too small to merit consideration.)

(d) Correction for displacement or buoyancy arising from the increased volume of the sphere, both in the air at \( \theta_i \) and in the steam at \( \theta_p \).

(c) Correction for unequal thermal capacities of the spheres.

(f) Reduction of the weight of the precipitation to vacuum.

Professor Joly's experiments show that in the case of air and carbonic acid the specific heat increases with the density, but with hydrogen the opposite seems to be the case.

For air the specific heat at constant volume at a mean pressure of 17-01 atmospheres, and a mean density of 0.0205, was found to be 0.1721. For carbon dioxide, the change with pressure is shown by the following table:

<table>

The mean result of the experiments on hydrogen gives a specific heat 2-402.

§ 6 (g) Dewar's Liquid Air and Hydrogen Calorimeter.—Dewar \(^1\) has devised a calorimeter based on an analogous principle to the steam calorimeter in which he employs one of the liquefied gases as calorimetric substance. Whilst Joly's calorimeter depends upon condensation on a cold object, Dewar's calorimeter depends on the evaporation as a means of absorbing heat from the hot object. Instead

of weighing the quantity of gas evaporated, he determines the volume of gas given off from the liquid which, of course, is at its boiling-point. Now the choice of liquidated gas to be employed as calorirometer substance is determined mainly by two considerations:

(a) The quantity of gas given off by evaporation on the absorption of one calorie of heat, and

(b) The range of temperature available through which substance is cooled.

The table below summarises the data for some of the possible gases:

<table>
<thead>
<tr>

</tbody>
</table>

It will be observed that oxygen gives off 19.2 c.c. per calorie whilst ethylene gives only 7. Hydrogen gives off 88.0 c.c. and is particularly advantageous but for the fact that the manipulation is difficult. Although nitrogen is a little better than oxygen, it is preferable to use the latter for the following reason. The boiling-point of air is below that of oxygen. Even if there is no layer of cold oxygen or gas on the surface of the liquid oxygen, the air coming in contact with it through the neck of the calorimeter would still remain gaseous; but if liquid nitrogen is used as caloriometer substance, air, being heavier than nitrogen but having a higher boiling-point, would, in falling down the neck of the calorimeter, come in contact with the cold gaseous nitrogen and be condensed.

§ (7) THE LIQUID OXYGEN CALORIMETER.—
It consists essentially of a large vacuum vessel A (Fig. 5) capable of holding two or three litres, into which is inserted the calorimeter, a smaller vacuum vessel B of 25 to 50 c.c. capacity, which has been sealed off from the long narrow tube G, projecting almost entirely from the mouth of A, and held in its place by a loosely packed cotton-wool. From the extremity of this narrow tube, either before or on passing out of A, a branch tube E is taken to enable the volatilised gas from the metal to be collected in the receiver F, water, oil, or other suitable liquid. To the extremity of the projecting tube G & test-tube C, in contains the portions of matter experimented on, is attached by a piece of flexible rubber-tubing D, thus forming a movable joint, which can be moved so as to tilt a few small pieces of substance contained in G into the calorimeter, and which afterwaeds assumes a position of somewhat like that in diagram.

With care it is possible to employ only a single piece at a time from G into B; but an improvement of this arrangement is shown in C12. In D, a similar arrangement is made, the portions of matter experimented on at the temperature of the room; but when temperatures are required initially, a vacuum vessel H, containing either solid carbonic acid, ethylene, air, or other gas, can be placed or enveloped the test-tube G to C1; or if higher temperatures are required, the surrounding vessel H is filled with the vapours of water or other liquids.

Now, when a quantity of liquid air has been so long volatilisation for a time, as the nitrogen (water) comes more quickly than the oxygen the boiling-point rises slightly. Two points require attention consequence of this: first, the maintenance constant temperature of the liquid air during series of experiments; next, the prevention a tendency for the caloriometer B to suck in some of the already volatilised gas. Hence exterior vessel A should be filled with a quantity—say two litres—of cold liquid air, taking a high percentage of oxygen, and the latter itself should be filled with some of this fluid. This will maintain very closely the constant temperature required. When any “shocking in” seems to be taking place, the caloriometer should be emptied and filled anew from the larger tank. The tube between the caloriometer and the gas tank should be of the size of wide quilt tubing, and lower end should be arranged to hold the end of the liquid in the collecting vessel as to give residual pressure. With such precautions, we may easily be obtained correct to within 2 per cent.

The instrument having been set up nearly with liquid air, an experiment is commenced by filling up the little test-tube, prov
CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

...calorimeter, a portion of any substance previously weighed. The substance in this way falls from the temperature of the room to that of liquid air. The heat given up by it volatilises some of the liquid, which is carried off by the branch tube and measured in the graduated receiver F. Immediately preceding or following this observation, a similar experiment is made with a small portion of a selected standard substance, usually lead. The quantity of lead is so chosen as to produce about the same volume of gas in the receiver as that supplied by the portion of substance experimented on. By this means the circumstances of the two observations are made as similar as possible, and thereby many sources of error are eliminated.

§ (8) LIQUID HYDROGEN CALORIMETER.

In 1913 Dewar further developed the method so as to adapt it to the range of temperature between the boiling-points of liquid nitrogen and hydrogen: from -196° to -235° C., a range of only 6°.

The liquid hydrogen calorimeter is a glass cylindrical bulb vacuum vessel A (Fig. 6) of 60 c.c. capacity, silveryed, with 1 cm. slit. On the neck is sealed a glass tube B. This projects through the brass coned fitting cap F of an ordinary silvered vacuum vessel in which it is supported. A side delivery tube, provided with stopcock D, is sealed near the top of B. A short length of rubber tubing on the neck of F makes a gas-tight joint with B. To minimise splashing, and to reduce the impact of the falling pieces, a thin strip of German silver or lead E, bent out near the top into a shoulder about 1 cm. square, stands centrally in the calorimeter A. The strip is cut from a thin tube of about the same diameter as the calorimeter neck. A short length of the tube is left above the shoulder, and supports the strip by fitting loosely into the neck of A. Some such device is essential in the use of this form of the liquid hydrogen calorimeter.

The calorimeter in its turn is immersed in liquid hydrogen in the supporting vacuum vessel C, the neck of the calorimeter being 8 to 10 cm. below the liquid hydrogen surface. The vacuum vessel C is only slightly wider than the lower part of A, and is provided with a coned cap F, whereby it is also supported and completely immersed in a wider vacuum vessel containing liquid air. C is also fitted with a brass coned cover, fitting vacuum-tight on to the cap F on C. Both caps are pierced by two thin tubes, one for fitting on to the filling syphons, the other, bent at right angles, serving for connecting to the exhaust in the case of the liquid air vessel, and in the case of the liquid hydrogen to the stopcock leading the evaporating hydrogen through the upper part of the apparatus.

This arrangement thus charged only needs a little liquid air sealed in every one and a half hour. The liquid hydrogen vessel will not need replenishing for at least four hours. The level of the liquid hydrogen in the calorimeter does not fall 1 cm. in six hours with constant use. The bulk of the materials added roughly compensates for the volume of the liquid hydrogen evaporated.

It is important that this level should not materially change, since, after striking the shoulder, realities move more slowly, are detached on to the cold wall, and low results are obtained due to the longer cooling of the materials in the vacuum before being immersed in the liquid hydrogen.

![Diagram of liquid hydrogen calorimeter](attachment:image.png)

The isolation of the calorimeter was such that less than 10 c.c. of hydrogen gas was evaporated from it per minute. The whole apparatus is supported between the cork-lined spring jaws mounted on a heavy metal base on which the outer vacuum vessel rests.

The cooling vessel H is connected by an india-rubber tube to the top of the calorimeter. It consists of an ordinary cylindrical silvered vacuum vessel, 20 cm. long and 7 cm. wide, with a central axial open tube K sealed in below. This tube passes through the liquid...
in the vacuum vessel. It has the same diameter below as the neck tube of the calorimeter. Near the top of the central tube a side tube D, of about the same diameter and similar form, serves for the introduction of the weighed pieces of material, which are all moved previously to the temperature of liquid air, and then fall on to a thin metal disc P fitting loosely the tube K, where they remain about 15 minutes. P is supported by being clamped to two thin platinum rods, L and M, fixed to a brass fitting connected on to the top. The rod L is not fixed directly to the disc but to a metal ring R. From the ring R two thin vertical steel wires are connected freely to two points on the circumference of the pan below. This rod and the attached ring can be given a vertical motion by a small N in the top fitting, thereby tipping the pan and releasing the piece of material, which then falls freely down into the calorimeter. A high vacuum is maintained by a cross-tube S, opening to the annular space, filled with charcoal.

At the temperature of boiling nitrogen, the convection currents in the central tube of such a vessel, when connected to the calorimeter below, have no serious effect on the temperature in the tube at a reasonable distance from the bottom, provided the central tube is not too wide. With a larger central vessel the width of the central tube was increased to 2-2 cm., and even here the difference was under 3° at the level of the pan. These temperatures were measured by a small helium thermometer, consisting of a 4-cc. bulb to which was sealed a small mercury manometer of thin capillary tubing.

The hydrogen evaporating from the liquid in the vacuum vessel C, in which the calorimeter is immersed, is employed in the interest of observations to maintain a hydrogen atmosphere through the neck of the calorimeter and the annulated measuring tubes. Little of solid air in the calorimeter neck is thus obtained. A simple arrangement of a three-way stopcock allows this to be manipulated.

The vessel V consists of a glass tube 8 cm. in diameter and 40 cm. long, open at the bottom and provided with a wide T-piece at the top. The tube is immersed to the neck in water in a glass cylinder, and is counterpoised by a weight and cork running over a pulley just above. It is thereby readily raised during the time gas is being evaporated from the calorimeter; this ensures that no back pressure is produced. One arm of the T-piece is open and connects to the stopcock on the calorimeter neck; the other is provided with another small stopcock and connects to a 20-cc. gas burette W similarly immersed in water. This latter stopcock is closed while the gas evaporated during an experiment is collected.

These arrangements are necessary to secure the minimum impingement to the surrounding hydrogen, which is usually evolved in less than 10 seconds, any temporary back pressure being fatal to concordant results. At least 15 seconds are allowed for collecting the gas given off, and even longer, in some cases, with badly conducting bodies.

As far as possible the materials used were cast in the forms of spheres about 8 mm. in diameter.

In the case of liquid bodies, the mould was first cooled by liquid air. Frequently liquids were frozen into solid cylinders in thin glass tubing, and pieces cut off after removing the glass mould. The metallic materials in some cases fused into buttons of convenient weight in an exhausted quartz tube. The load, however, of which many pieces were required, was cut from rod, and subsequently squeezed in a small spherical mould.

Volatile bodies were weighed at a low temperature on a light German silver pan supported by a thin platinum wire suspension from the balance pan about 2 cm. above the level of liquid air contained in a wide deep vacuum vessel. Some materials would not make coherent buttons or cast sticks, and these were filled into very thin-walled cylindrical metal capsules.

In order to obtain consistent results it is necessary to employ exactly the same procedure in each test, but with this apparatus Dewar was able to obtain results which rarely varied among themselves by more than 2 or 3 per cent.

The data thus obtained for the mean specific heats of 53 elements at about 90° abs. are summarised in Table V.

</table>

The interesting fact discovered in the course of this investigation was that the atomic heats were periodic functions of the atomic weight, and the curve resembled, generally, the well-known Mayer atomic volume for the solid state.

56.

CALORIMETRY, METHOD OF MIXTURES

§ (1) Introduction.—Calorimetric apparatus assumes the most diverse form, each type characterized by certain features, which adapt it especially for a particular class of measurement.

For the determination of the mean specific heat of a substance over a range of temperature or for the determination of the heat of combustion of a fuel the Method of Mixtures is a convenient one to employ and is probably the best known of all calorimetric methods.

§ (2) The Method of Mixtures.—The principle of this method is to impart the quantity of heat to be measured to a known mass of water contained in a vessel of known thermal capacity, and to observe the rise of temperature produced; from which data, as explained in detail farther on, the quantity of heat can be calculated. This method is the simplest of calorimetric methods, but it is not the most accurate. Heat is lost in transferring the hot object to the calorimeter, and although it can be minimized by arranging that the transfer takes place rapidly, it cannot be eliminated or even accurately allowed for. Some heat is lost when the calorimeter is raised above the temperature of its enclosure and before the final temperature is reached. This can be roughly estimated by observing the rate of change of temperature and assuming that the heat loss is directly proportional to the duration of experiment and to the average excess of temperature. The accurate determination of this correction is of fundamental importance in this method and a detailed discussion of it will be given. It is always desirable to diminish the loss of heat as much as possible by polishing the exterior of the calorimeter to diminish radiation, and by suspending it by non-conducting supports inside a polished case to protect it from draughts.

It is also very important to keep the surrounding conditions as constant as possible throughout the experiment. This may be secured by using a large water-bath around the apparatus, but in experiments of long duration it is advisable to use an accurate temperature regulator. The method of logging the calorimeter with cotton-wool, which is often recommended, diminishes the heat loss considerably but renders it very uncertain, and should never be used in work of precision, since the heat conductor takes so long to reach a steady state that the rate of loss depends on the past history more than on the temperature of the calorimeter at the moment. A more serious objection to the use of logging of this kind is the danger of its absorbing moisture.

Regnault about 1840 made a careful study of the Method of Mixtures, and by skill and attention to detail he obtained means of it a valuable series of thermal data. It is only within comparatively recent years that any material improvements on Regnault's apparatus have been effected.

§ (3) Theory of Method of Mixtures.—

It will be assumed that the cases under consideration are those of solids and liquids.

The determination of the specific heats of gases requires especial consideration and is dealt with in a separate section.

Let M = mass of heated body,

\( \theta \) = temperature of heated body at the moment of its immersion in the water of the calorimeter,

W = mass of water employed,

\( t \) = temperature of water when the body is immersed in it,

\( T \) = temperature when the thermal equilibrium is established between the body and the water, i.e. when temperature of water ceases to rise (or sink if the body was colder than the water).
CALORIMETRY, METHOD OF MIXTURES

Now if \( a \) = mean specific heat of water between \( T \) and \( t \), and \( S \) = specific heat of the body between \( \theta \) and \( T \), we get

\[
M(S(\theta - T)) = W(a(T - t)),
\]
and

\[
S = \frac{W(a(T - t))}{M(\theta - T)}.
\]

This gives the calorimetric equation for the method of mixtures in its very simplest form; for practical working several corrections are necessary.

(i) For \( W \) we must substitute another magnitude \( W_1 \) such that \( W_1 = W \cdot a \) = mass of water, having the same heat capacity as containing vessel, stirrer, etc. and all parts whose temperature is undeniably affected:

\[
W_1 = W + r \cdot \frac{a}{\theta},
\]
and in this case equation (a) becomes

\[
S = \frac{W(a(T - t))}{M(\theta - T)} \cdot \frac{a}{\theta}.
\]

Sometimes the substance has to be supported in a receptacle, and if we put \( u = \) water equivalent of such receptacle and taking \( a = 1 \) within the limits of the experiment, we get

\[
S = \frac{W(a(T - t))}{M(\theta - T)} \cdot \frac{a}{\theta}.
\]

Where the results are to be as accurate as possible, equation (c) takes a more complicated form. In addition to the magnitudes already represented, we have to take account of the thermal capacity of the thermometers, etc.

In addition to these corrections dependent on the nature of the various parts of the apparatus, there is the cooling correction for the loss of heat from the calorimeter to its surroundings.

§ 4 MODERN APPARATUS FOR THE METHOD OF MIXTURES—The complete outfit required for experiments with the method of mixtures consists of the following elements, which will be considered individually:

(i) The calorimetric vessel and the device for mixing the contents.
(ii) The jacket enclosing the calorimeter.
(iii) The thermostat for measuring the temperature rise of the water.
(iv) The apparatus for heating or cooling the charge (in specific heat determinations).

§ 5 CALORIMETERS AND STIRRERS. (I) The Calorimeter—The calorimeter is usually made of pure copper, nickel plated and polished as much as to reduce radiation to a minimum.

The use of a vacuum jacket as a calorimeter is not to be recommended for ordinary work. Undoubtedly it is possible by means of it to reduce the magnitude of the cooling rate, but this advantage is more than counterbalanced by the disadvantages of this form of container due to its brittleness, the lag of the portions of the glass walls above the surface of water, the difficulty of overbalancing its heat equivalent, and of keeping it constant.

Under certain circumstances the use of water or other calorimetric fluid becomes impracticable. Hence some investigators have employed as calorimetric thick-walled metallic cups and trusted to the high coefficient of heat conductivity of the metal to equalise the temperature. Those special forms of calorimeters are described later.

(ii) The Stirrer—Stirrers vary considerably in design according to the specific purpose for which they are required. A typical form is illustrated in Fig. 1; here a screw is employed for stirring the contents. The vessel is constructed with an \( \infty \) - shaped cross-section, the stirrer being contained in a tube which is connected with the main tube at the top and bottom. By this arrangement it is possible to ensure a steady circulation through the calorimeter, and it is advisable to direct the stream as smoothly as possible by suitably curved passages.

In the design of such a calorimeter a particular attention must be given to the provision of wide passages for the circulation of the water and care taken to avoid as far as possible dead spaces. It might be remarked that this method of stirring has been found to be the most reliable for calomel balls for mercury thermometers and is much superior to a plain screw in a vessel of liquid.

White \(^1\) adopted a somewhat similar form of calorimeter for his experiments on the specific heat of silicates at high temperatures. The charge, contained in a platinum vessel, was dropped directly from the furnace into the calorimeter.

It will be observed from Fig. 2 that the cover \( W \) is in actual contact with the water to ensure temperature equilibrium. The angular space over the cover permits the water to vary somewhat in amount without over-flowing or failing to wet the cover, while the weight of the cover (70 grms.) prevents it from being floated out of the place where the water is high. An approximate preliminary adjustment of the amount of water is of course necessary, and is very easily obtained. Evaporation through the joint is about 7 mg. an hour, which is not likely to produce appreciable error. An oil seal gives very little trouble, and is used when maximum accuracy is desired.

CALORIMETRY, METHOD OF MIXTURES

(b) Absorbed moisture if the surface is hygroscopic.
A,tinushed copper surface 100 cm. square in area will absorb 7 milligrams of water in a saturated
atmosphere at ordinary temperature, whilst a surface of polished nickel of the same size and under the
same conditions will absorb as much as 0.1 milligram. Hence it is always advisable to provide
the calorimeter with a lid, although it will be found that to show the calorimeter effectively the addition
of a lid complicates the construction.
Even with the simplest form of apparatus a
substantial improvement is produced by providing
a lid of very thin metal having a slot to allow of its
being removed for the introduction of the hot body
without disturbing the thermometer.
§ (6) THE JACKET SURROUNDING THE CALORIMETER.—While 1 during the course of his
extended researches on the specific heats of the silicates has devoted much attention to
the design of the calorimetric appar-atus employed.
One form of jacket for maintaining a constant
temperature envelope around the calorimeter which he has de-
scribed is shown in Fig. 5. The
jacket is shown in section and also in top view,
partly open. Water is held in
the two halves of the cover, and
in the upper section of the chamber wall, by
the propeller the water
divides and passes across through
the three upper passages, and then returns through the
lower space. Its circulation is directed by the
pumps E and Q, of which Q runs nearly
the whole length of the tank outside the
chamber, as shown by the dotted line. The
chamber is opened by moving the covers
wide; their down-turned ends then move in the
lugs left at the ends of the tank.
The covers slide upon the stout rod T. The pulley
for the calorimeter stirrer, and the whole
jacket stirrer, are borne on one half cover.
This half is channeled firmly in place during an
observation ; moving aside the other fully
exposes the calorimeter opening.
(1.) Method of supporting the Calorimeter.—
Heat transfer between the calorimeter and its
jacket may take place in four ways—
by conduction, convection, radiation, and
evaporation. The object of applying the cooling
correction is to eliminate this heat from the final result.
Whilst in practice it is not necessary to
study these effects separately, it might be
remarked that under ordinary conditions the
greater portion of the heat transfer is due to
convection and air conduction, the two together
constituting about 80 per cent of the total.
It is advisable to reduce the transfer by
thermal conduction through the supports of the
calorimeter to a minimum since it constitutes an unmeasurable source of error.
Consider, for example, the case of a calorimeter supported within the envelope on a
sheet of cork or rubber. When the calorimeter and envelope are at two steady temperatures the
heat transfer is, by the laws of conductance, proportional to the temperature difference ; if
however, the temperature of the calorimeter is changing rapidly the rate of transfer is not
exactly proportional to the temperature difference.
The following is a discussion of this source
of error by Distin; 2
Since the conductivity of such materials is
always small, compared with that of the
metallic sheets in contact with them, the
temperatures of the surfaces may be taken, for
the purposes of this discussion, as approximately the same as the measured temperatures of
the calorimeter and the jacket respectively.
The distribution of temperature in each layer and the rate at which heat is leaving the
calorimeter at any time may be then determined from the following considerations:

A sheet of material of thickness e bounded by
plane surfaces s and s is initially at temperature θo.
If x and θ are each taken as 0 for convenience, and
the temperature of one of the surfaces s or s is then
raised from θ to θ in such a way that
θ = θ(1 - e^(-ax)), the temperature distribution in this
plate is given by the following equation:
θ = θ(1 - e^(-ax))

(1)

Where θ is the thermometric conductivity of the
material, θ(0) is the temperature of the front x = 0,
taken here as θ(1 - e^(-ax)).

The point of interest in this discussion is the rate
at which heat is leaving the calorimeter at any time,
as this determines the value of the emissivity for
the portion of the surface in question. If ω and e are each made unity, and the above expression for
θ is differentiated with respect to x, the following

| Combustion, Calorimetry, and the Laws of

Combustion of Coal Smoke, Benzole Acid, and

253.

2 W. H. Quaterly, "Fourier's Series and Elliptic

Harmonics," p. 110.
CALORIMETRY, METHOD OF MIXTURES

expression for the temperature gradient at any point in the material is found:

\[ \frac{\partial t}{\partial x} = e^{-at} \]

\[ \frac{\partial^2 t}{\partial x^2} = \frac{a^2 e^{-at}}{1 - e^{-at}} \]

The surface \( x = 1 \) is the surface in contact with the calorimeter, so that substituting this value of \( x \) and the appropriate values for \( a \) and \( t \), the above expression gives the temperature gradient in the material in contact with the calorimeter, which is proportional to the factor \( k \) for this portion of the surface.

As an example showing the effect of this kind of equation, suppose that the calorimeter rests on a sheet of charcoal 1 cm thick and that the temperature in the calorimeter rises quite approximately according to the relation

\[ \theta - \theta_0 = (1 - e^{-at})\theta_0 \]

where \( \alpha = 0.03 \) and \( \theta_0 \) and \( \theta \) represent, respectively, the temperatures at any time, the initial, and the final temperature. The value of \( \alpha \), the thermometric conductivity, for charcoal is approximately 0.001 in C.G.S. units. Hence quantities substituted in the above equation show that after 60 seconds the rate of heat loss is 2-75 times its final value, after 5 minutes the rate is 1-13 times the final value, and only after 10 minutes does it come to within 1 per cent of its final value, if the area in contact with such a strip were a considerable part of the whole area of the calorimeter, the error introduced from this cause evidently would be a very serious one. Such a distribution of material as here described will also have an effect on the heat capacity of the calorimeter.

This discussion shows that all non-conducting supports should be negligibly small, or, since the thermometric conductivity \( a^2 = K \rho p \) the absolute conductivity \( K \) divided by the specific heat \( c \) and density \( \rho \), the material used for them should have a small density and specific heat. A form of support should therefore be employed, in which the smallest possible mass of bounding material is used, with the smallest possible area in contact with the calorimeter. The mass of such supports can readily be made negligible compared with that of the calorimeter.

(ii) Supports and Space between Calorimeter and Jacket. To reduce errors due to the above causes to a minimum Dickinson 2 employed the following arrangement of supports for his calorimeter. The supporting plane's (three in number) were made up of a base cast molded to the bottom of the jacket, and a small ivory tip about 5 mm. in diameter centered into the end of the same and resting against small plates (one with a hole, one with a slot, and the third plane) on the bottom of the calorimeter. The thermal conductivity of the ivory tips is small, and their total space is not over 0.1 mm. so that their effect on the cooling rate is too small to be significant. The base comes, while they have a considerable mass, have a heat conductivity not great compared with the amount of heat which they can receive by radiation, convection, etc. (about 14000 B.T.U. per degree centigrade per second per degree temperature difference, that their temperature is at all times lower.

1 Value found by experiment by Dickinson for his calorimeter.
2 See ref. 1.

(iii) Heat Conduction along the Stirrer. The steel stirrer shaft which enters the calorimeter should just above it in a thin rubber sleeve, which should fit tightly over it and tightly within a larger steel piece coupled to the driving shaft. It is evident from a thermometric conductivity of steel is many times greater than that of the hard rubber sleeve, the temperatures of the two metal parts will remain very nearly the same as the temperatures of the calorimeter and the jacket respectively. The heat capacity of the rubber sleeve, some of which should be added to that of the calorimeter, is insubstantial.

§ (7) Method of Calculating the Cooling Correction. (i) Ranfurd. Ranfurd was the first to introduce a method of correcting for the heat loss from the calorimeter. His procedure was to make a preliminary experiment to ascertain approximately what the rise of temperature would be and then to cool the calorimeter half this number of degrees below the temperature of the surrounding atmosphere before the next experiment. For example, let

\[ \theta_t = \theta_f + \theta_0 \]

The calorimeter is cooled to \( (\theta - \theta_0) \), and the heated body then introduced; the maximum temperature will be approximately \( (\theta + \theta_0) \) and Ranfurd's idea was that the amount of heat gained by the calorimeter during this time its temperature was below \( \theta \) will exactly compensate for the amount lost by it while its temperature was above \( \theta \). This is approximately true, but not quite so, owing to the fact that the rate of increase of temperature diminishes very rapidly as the heated body and the water approach thermal equilibrium; thus, it may happen that the rise of temperature from \( (\theta - \theta_0) \) to \( \theta \) will occur in less than 20 seconds, while the rise from \( \theta \) to \( (\theta + \theta_0) \) will occupy over 100 seconds.

(ii) Arithmetic Method of computing Heat Loss. A far more accurate, but not nearly so very a method of correction is the following: On the calorimeter are several degrees below the calibration and take very careful readings at intervals of about 20 seconds before and after the introduction of the hot body, and also after the establishment of thermal equilibrium between the hot body and the water. Let \( \theta_1, \theta_2, \theta_3 \ldots \theta_n \) be the temperatures of the calorimeter at the beginning and at the end of \( n \) periods of say, 20 seconds each before the introduction of the hot body.

Let \( \theta_1, \theta_2, \theta_3 \ldots \theta_n \) be the temperatures for \( n \) periods of equal duration after the introduction of the hot body up to the establishment of thermal equilibrium between the hot body and the water.

Then \( T_1, T_2, T_3 \ldots T_n \) be the temperatures for \( n \) similar periods after the establishment of thermal equilibrium; \( t_1 \) and \( T_2 \) are virtually the same. This temperature \( t_1 \) should not be taken from the reading
of the thermometer, but should be calculated as follows:

\[ t = \theta_0 + \frac{\theta_m - \theta}{\ln \frac{\alpha}{\alpha_1}} \]

During the first interval after the introduction of the heated body the mean temperature of the calorimeter has been \( t + \frac{1}{2} \theta \), and if we put \( \alpha \) for the change in the temperature of the calorimeter due to its surroundings we get for the first interval

\[ t_1 - a \left( \frac{t + \theta}{2} - x \right) \]

where \( a \) and \( x \) have to be calculated. For the second interval we have

\[ t_2 - a \left( \frac{t + \theta}{2} - x \right) \]

where \( a \) and \( x \) have the same values as in the expression for \( t_1 \). Finally,

\[ t_n = a \left( \frac{t + \theta}{2} - x \right) \]

so that between \( t \) and \( t_n \)

\[ \Sigma x_n = a \left( \frac{t + \theta}{2} - x \right) \frac{1}{n} \]

The values of \( a \) and \( x \) are found in the following way: Let \( \phi \) represent the mean temperature of the calorimeter before the introduction of the hot body,

\[ \phi = \theta + \theta_0 + \theta_1 + \ldots + \theta_n \]

so that the mean value of \( v = a (\phi - x) \) between \( \theta \) and \( \theta_n \) and putting \( \phi \) for mean temperature after establishment of thermal equilibrium,

\[ \phi = \frac{T + T_1 + T_2 + \ldots + T_n}{1 + \frac{1}{n}} \]

and the mean value of \( v = a (\phi - x) \).

Now \( v = \frac{\theta - \theta_n}{n} \) and \( v' = \frac{T - T_0}{r} \).

From the two equations \( v = a (\phi - x) \) and \( v' = a (\phi - x) \) we get

\[ \phi = a \phi ' \]

and

\[ x = a \phi ' - \phi \phi ' \]

from which \( \Sigma x \) can be calculated, and hence the corrected value of the change of temperature of the calorimeter.

\( \text{i} i i \) Graphical Method of determining the Heat Lost.—A graphical method of computing the cooling correction is due to Rowland.

\( \text{a) Rowland's Method}.—\) Instead of finding the number of heat units lost by the body while the temperature of the body is rising to its maximum value, the heat lost is accounted for if the temperature is which the body would have attained had been no less. The correction is as follows: First make a series of points of the temperature of the water calorimeter, before and after the body has dropped in, together with the time, and then plot them graphically on a large sheet of paper. Fig. 6. From or on continuations of the ordinates are sufficient, noted is the temperature of the water of the time being plotted horizontal temperature vertically. Continue until the meeting line a horizontal through the point of the curve, draw \( n \) also a vertical line by; lay off \( e \) and draw the line \( f \) through \( e \) which indicates the temperature of the vessel used in the calorimeter. Draw a vertical line \( k \) from the point of maximum a line \( f \) parallel to \( d n \); where will then be the required point for rise of temperature, corrected for all cooling errors, will be \( l k \).

This method, of course, only applies to cases where the final temperature of the calorimeter is greater than that of the air; otherwise there will be no maximum.

\( \text{b) Perry's Method}.—\) In a modification by Perry of Rowland this temperature can be obtained by a simpler construction.

Let \( \alpha \) represent the temperature in the surroundings, and let a body at \( e \) below these be given a quantity \( \alpha \) so that its temperature rises to \( f \). The way in which the temperature before the heat \( H \) is added is shown by the lines \( A B \) in Fig. 7. This shows how the temperature changes as \( \alpha \) is absorbing the heat \( H \).

\footnote{\textbf{On the Mechanical Equivalent of Heat, with Subsidary Researches on the Variation of the Temperature from the Air Thermostat, and on the Variation of the Specific Heat of Water.} \textit{Proceedings of the American Academy of Arts and Sciences}, 1890, xx. 74-250; also \textit{Physical Papers}, p. 402.}
body is, in addition, receiving heat from the surroundings, and from C to D is losing heat to the surroundings. The line DE indicates the temperature changes due to radiation, etc., alone.

Through C draw a vertical line. Prolong ED backward until it cuts this vertical in \( f \). Prolong AB forward till it cuts the vertical line in \( k \). Then the temperature changes are given by \( hf \).

To see that the above method of finding the desired temperature is reasonable, consider the following: If the heat \( H \) had not been given to the body, it would have continued to rise in temperature in the same way that it was rising from \( A \) to \( B \), so that by the time it really attained the temperature indicated by \( C \) it would have reached the temperature indicated by \( h \); that is, while the body really rose in temperature from \( B \) to \( C \) the rise in temperature from \( B \) to \( h \) was due to heat from the surroundings, and the rise from \( h \) to \( C \) was due to a part of the heat \( H \). Again, if the body had not been given the heat \( H \), but if it had been at first at such a temperature that as it cooled it reached the temperature indicated by \( D \) at the same instant that it really reached that temperature—and thereafter cooled as shown by \( DE \)—it would have been at a temperature \( f \) at the instant when it really was at the temperature \( C \); that is, while the body really rose in temperature from \( C \) to \( D \) the full in temperature due to radiation was the fall from \( f \) to \( D \), so that if there had been no loss of heat by radiation the rise of temperature during this time would have been from \( C \) to \( f \). Hence, if there had been no gain or loss of heat by radiation the body would have risen in temperature the amount indicated by the distance from \( h \) to \( f \).

While the temperature of the body rose from \( C \) to \( D \) it was really at a lower temperature than if it had been cooling from \( D \) to \( C \), and so did not really lose as much heat by radiation as has above been supposed. Hence, the point \( f \) is higher than it ought to be. For a similar reason \( k \) is also somewhat higher than it ought to be. If the time from \( B \) to \( C \) is about the same as that from \( C \) to \( D \), these two errors will nearly balance each other.

(iv.) Adiabatic Method. — To eliminate entirely the necessity for correcting for the heat transfer between the calorimeter and its jacket, T. W. Richards 1 has devised various forms of calorimeters in which the bath surrounding the calorimeter is kept throughout the experiment at an equal or equivalent temperature. This device has been found to be particularly convenient in experiments on heat of dilution, heat of reaction, and recently it has been adapted for fuel calorimeter work. The precise method adopted for heating the jacket to keep it in step with the calorimeter varies. Richards has used the heat liberated by chemical reaction of the same character as that under test in the calorimeter. For most purposes, however, electrical heating is the more convenient. It is usually necessary to make a few blank experiments to settle the relative values of the current, so the method finds its greatest field of application when a large number of experiments have to be performed. Since the stirrer in the calorimeter generates an appreciable amount of heat, it is convenient to keep the temperature of the jacket at a temperature of a degree or so below that of the calorimeter, so that the residual heat loss just balances that generated by the stirring. Whilst the device cannot give greater absolute accuracy than that in which a stationary jacket temperature is employed, it has the advantage that the initial and final temperatures are stationary and hence more easily measurable with resistance thermometers than would be the case if the temperature were moving.

§ (8) Thermometer for Measuring the Temperature Rise of the Water. — The most generally used instrument for the measurement of the temperature rise of the calorimeter is the mercury thermometer, but in work of precision the resistance thermometer is to be preferred. Experience has shown that the inherent defects of the mercury thermometer limit the possible accuracy to 2 or 3 parts in 1000 for a 2° rise of temperature, while with a suitable resistance thermometer outfit ten times this accuracy may be obtained, but of course it necessitates an expensive equipment and more labour with the observations. For a discussion of calorimetric mercury thermometers reference should be made to the articles on “Thermometers” and “Resistance Thermometers.”

§ (9) Appliances for Heating or Cooling the Charge. (l) Steam Heater.—Regnault in his extended series of experiments used a steam-jacketed heater to bring the charge to 100° before dropping it into the calorimeter. His form of heater consisted merely of a boiler with a tube containing the charge, and on inverting it the heated charge is dropped into the calorimeter. White has modified the Regnault heater to the form shown in Fig. 8 which is self-explanatory. He employs electrical heating, since then it is possible to

move the apparatus about without danger of premature cooling. The apparatus is manipulated as follows: Just before discharging the temporary outlet is opened, the condenser and thermocouple removed, the opening stoppered, and lastly the heating chamber unstoppered and the charge dropped into the calorimeter. The object of the shallow cup below the chamber filled with condensed water is to shield the chamber against superheating. White points out that the usual practice of closing the upper end of steam heaters with cards is defective, since the ends are left comparatively cold, and consequently errors of the order of a few parts per 1000 may result.

(ii.) Electric Furnace.—For heating the charge to high temperatures some form of electrical furnace is generally employed, as this permits of the attainment of temperatures up to 1800° C. It is, of course, necessary to ensure that the furnace should give a uniform temperature over the region occupied by the charge, and experience has shown that the simplest method of effecting this is to wind the tube uniformly, and over each end add additional coils capable of independent control; thus, by adjusting the relative values of the current in the main circuit and the supplementary coils, a good degree of uniformity can be obtained. It might be remarked, however, that the ratio of the currents in the circuits which will give uniformity at one temperature may not necessarily apply to another, and consequently separate experiments are necessary to determine the heat values for each point.

In his work on the specific heat of silicates White employed a furnace with internal platinum winding. This has the advantage of permitting of the attainment of higher temperatures than is possible with a winding on the exterior of the tube, and also diminishes the lag between the coil and the chamber, so that equilibrium is obtained with greater rapidity. This furnace (Fig. 8) is mounted on a stout iron plate with an air space beneath. An opening of 5-5 cm, is cut through the furnace bottom and plate, which is closed by a plug of fireclay carried on a movable iron plate. This is held up against a large plate

---

**Fig. 9.** Arrangement of calorimeter water jacket to shield the calorimeter against the cooling effect of the cool parts of the furnace: 88, water jacket; 8, latch for closing the furnace bottom; MM, heavy wires for dropping the charge; T, thermocouple.

**Fig. 10.** Arrangement of mantled material and platinum for automatically dropping the platinum container, Fig. 8.

L, latch; V, Its interior; MM, tubes, about 8 mm. in diameter; W, wire, whose pull unlashes the bell of the container; CT, charge thermometer; FT, furnace thermometer; FT, furnace winding; FI, furnace shield. The platinum tube around CT in the container is supposed to be cut away. L is 23 mm thick. MM were covered with sheet platinum, which was part of the equipment shield.

by the latch in such a way that a quick pull on the latch causes the plug to fall away without tipping. Upon the block and inside the furnace chamber is a pedestal made up of three firebrick partitions each faced on both sides, except on the sides facing the crucible, with reflecting discs of platinum foil, and supported by a light frame made by grinding away as much as possible from the thin porcelain tube. This pedestal has two functions. It protects the crucible from the cooling effect of the furnace bottom and it also supports the crucible during the period necessary to reach the constant temperature. Platinum is very soft at high temperatures, and the fine wires which support the crucible for an interval of 1 second, which elapses between the fall of the crucible and the pedestal, would have to be very large if they were to hold for any length of time. At
the higher temperatures the uppermost partition is not to stick to the bottom of the crucible, hence it is held by platinum wire to the plate below, the weight of which is enough to pull it away. Above the crucible another platinum partition is suspended. When the potential falls from the furnace it is caught in a light wooden box, which can be pushed out of the way, and at the same time switches off the furnace current.

The simplest method of supporting the charge in the furnace is to use a loop of platinum wire and fuse it by a strong current when it is desired to drop the charge into the calorimeter. This method was used successfully by Parker 1 in his experiments on the specific heats of iron.

White found some difficulty with the fused wire method of making a release at temperatures above 1000° C. owing to the arcing which occurred across the terminals after the wire was melted. This difficulty could no doubt have been overcome by making the current fuse a length of copper wire outside the furnace the same time as the supporting wire inside. He, however, devised a mechanical drop for releasing the charge. This was made of iron, the upper end being in the form of tubes and plates. The complete arrangement is shown in Fig. 9. Steel platinum wire of 1.2 mm in diameter was attached automatically to release the container as the wali of the shield of the furnace was swung on one side. This was found to be generally satisfactory, but many troubles were encountered owing to insufficient rigidity of the supports, combined with a too rapid swing of the shield.

§ (10) THE SPECIFIC HEATS OF SILICATES AT HIGH TEMPERATURE. — With this above-described apparatus White 2 has made an extensive investigation of the heat capacity of various silicates at high temperatures. The data obtained are summarized in Table I, from which the "instantaneous" atomic heats have been calculated by the procedure described below:

### Table I

The method of experiment gives the mean specific heat over a wide range of temperature and is not suitable for giving with accuracy the true specific heat, if this changes rapidly with temperature, as is the case at very low temperatures. At high temperature, however, the relation between specific and temperature is practically linear, hence it is possible to calculate the “instantaneous” or true specific heats with fair accuracy, as follows:

If the interval specific heat is sufficiently well expressed by polynomial equations with a constant, $A + B^2 + C^2$, etc., where $d$ is the constant temperature, the total heat from $0^\circ$ $C$ up is $A + B^2 + C^2$, etc., and the true specific heat at any temperature, which is the differential of the total heat, is $A + 2B^2 + D^2$, etc., so that the quantity which must be added to the mean specific heat to get the true heat is

But in a series of 4th-degree polynomials each first difference is

$$B^2 + 2B^2 + DB^2 \left( \frac{B^2}{4} \right) + DB^2 + \frac{B^2}{4},$$

each 3rd difference is $1B^2 + 2B^2 + 3B^2$, where $P$ is the temperature interval between each two successive values in the series. It follows at once that by subtracting $\frac{3}{2}$ of the 3rd difference from the 1st, and then multiplying by $\frac{3}{2}$, the difference of true and integral heats is obtained. The method is readily equivalent to obtaining a series of 4th-degree equations and thus computing the true specific heat, but is much easier.

For quartz and silica glass the values of the interval specific heat to $100^\circ$, $300^\circ$, and $500^\circ$ satisfy the expressions:

- **Quartz**
  - $0.165 + 0.0001949 - 0.000000116^2$
- **Silica Glass**
  - $0.1670 + 0.0001890 - 0.0000001265^2$

**§ (11) Low Temperature Apparatus.—**

Experiments at low temperatures cooled down the substance under test in a quartz vacuum vessel, through which passed a tube open at both ends, as shown in *Fig. 11*. This tube was surrounded by liquid air or a mixture of alcohol and solid CO$_2$. The device is operated as follows: As soon as the equilibrium of temperature has been obtained, it is placed over the calorimeter. A slide is opened and the contents, suspended on a thread, are let down into the calorimeter.

Instead of the expensive quartz vessel the following simple device may also be used (*Fig. 12*). In a large glass tube A is placed a tube J, somewhat enlarged at the bottom and closed at both ends. The tube is immersed in the constant temperature bath. The time required to obtain the equality of temperature may be shortened by passing through a slow current of dry hydrogen, which flows into the outer vessel through a small channel in the lower cork and then into the air through the cotton-wool. To bring the substance into the calorimeter the whole device is lifted into the neighbourhood of the calorimeter, which is then opened. The inside tube J is rapidly removed from the test tube, the lower cork taken away, and the other one slightly lifted so as to allow the container to drop into the calorimeter. The whole manipulation takes about three seconds. In that time the substance is only slightly warmed up. With liquid air, for instance, it is claimed that the heat loss is hardly 1 per cent.

**§ (12) The Thermal Unit and the Variation of the Specific Heat of Water with Temperature.—** It is customary to express heat quantities in terms of the heat capacity of water for 1° change of temperature, and
since this heat capacity is now known with
accuracy in terms of the primary units,
and it is possible to express heat quantities
in "engy" by the use
of an appropriate factor.
For a long time it was not fully realized
that the specific heat of water varied
with temperature, and consequently the practical
heat unit varied with the range of temperature
through which the water was heated when
employed as calorimetric medium, Even
when it became apparent that the specific
heat could not be regarded as constant the
data published did not permit the magnitude
to which the variation was re-considering that the experi-
ments were conducted implied in them in the
variation of their observations.
In later years the work of Rowlands (1870),
Bartoli and Scarlatti (1871), Griffiths (1881),
Ladub (1896), Callendar and Barnes (1902),
has proved conclusively that the form of
the specific heat-temperature curve is that shown
in Fig. 13, and that there is a minimum value
at 30° to 40° C.
Hence the calorie is only fully defined when
the particular degree (° C.) of temperature
out, and the temperature changes at the bulb 2
are determined by means of the thermometer.
To obtain heat in the block is introduced
into a lower vacuum vessel. The arrange-
ment is shown in Fig. 14. The block is
weighed about 300 grams, when inserted into a
block, by means of a bell-metal,
and the tube made of the glass vessel
which has been made as thin as possible. To
ensure that the block is held in the vacuum
vessel by means of Wood's lamina.
In the diagram Fig. 14 there are three points.
The junction of the two elements are im-
planted into thin walled glass tubes which are
fixed in holes in the block by means of bell-
metal. Good contact is made between junctions and
the tube are also obtained by the use of bell-
metal. The other junctions are in a
bell-shaped copper block, by which the vacuum vessel
does not come in contact with the instrument. This tube
can be closed by means of a
slide as shown. The whole
apparatus is submerged in a
constant temperature bath, usually in an oil
bath, and the temperature is main-
tained constant. To keep the
apparatus at right-angles to
the vertical, a graduated
metal rod is added. To prevent the
heated air from rising up to
the calorimeter, which means
a loss of heat after the sub-
stance has been weighed, a some
coated rod is placed on the top of the cylinder so as to
just close the holes in the copper block after the
material has been dropped in.
In their experiments the temperature
changes of the calorimeter were observed
from 20° to 35°, giving a good deflection of 10 degrees. To
obtain complete at the beginning of the reading the
must be calibrated to the point of zero, the heated
water being brought to a constant temperature
recorded and the time then repeated from time to time until
eliminate small errors.

(13) METALLIC BLOCK CALORIMETERS. (d)
Nernst. A calorimeter in which the metal
vessel of liquid is replaced by a heavy copper
block has been employed by Nernst, Elch-
mann, and Kessel for specific heat deter-
minations. The block is hollowed out, and the
material dropped into its interior. Being to
the good thermal conductivity of copper it
has practically the same temperature through

\[ \text{Fig. 13.} \]

\[ \text{Fig. 14.} \]
CALORIMETRY, METHOD OF MIXTURES

Place, who employed a calorimetric method based on the measurement of the quantity of ice melted. Later, Delaroché and Berard made some careful experiments in which a uniform current of gas, heated at 100°C, by passing through a tube surrounded by a vapour-jacket, was cooled by passing through a spiral contained in the calorimeter. The method was essentially that of mixtures, and most of the subsequent investigators adopted this method with various modifications to meet special requirements. Consequently, the published data are confined to the mean specific heat over a wide range of temperature. More recently Calerberg and his associates have developed the method of electrical heating which permits of the determination of the true specific heat.

Amongst the workers employing the method of mixtures Regnault stands pre-eminent. He brought to bear upon the subject his unique skill and experiences of calorimetric measurements, with the result that the data he obtained were accepted, almost without question, for the following half-century. There is, however, no doubt that the results given by Regnault were a little low, about 2.5 per cent, due to an inaccuracy in his method of determining the heat conducted into the calorimeter along the pipe through which the gas flowed. Without describing in detail Regnault's apparatus its essential features may be briefly reviewed.

The gas was contained in a large reservoir, heated up by passing through a long spiral immersed in an oil bath, and thence led to the calorimeter. Care was taken to ensure a uniformity of flow of gas through the calorimeter under constant pressure, and independent experiments were made to ensure that the gas leaving the calorimeter had cooled to this temperature. Since it was assumed that the temperature of the gas entering the calorimeter was the same as that of the heater, precautions had to be taken to avoid loss of heat by the gas in passing from the bath to the calorimeter, and at the same time prevent as far as possible conduction of heat from the bath to the calorimeter along the connecting tube.

The correction for the heat carried along this tube, which was made of low conductivity material, was deduced from observations of the change in temperature of the calorimeter without the gas flowing. This change of temperature is due to the combined effect of the conduction and the rate of heating or cooling of the calorimeter due to the difference in temperature between it and the surroundings.

If \( \Delta T \) is the observed rate of change of temperature per unit time, then \( \Delta T \) is equal to \( A - 100 \), where \( A \) is the excess of the temperature of the calorimeter over that of the room.

The instrument has not yet been developed to a stage when it can be used for routine tests, several sources of error which influence the readings not having been eliminated. One important factor is the pressure of the oxygen in the bomb. Should this pressure be below that for which the instrument has been calibrated, combustion will become slower and heat loss due to radiation, etc., will be greater than that under normal conditions. A few typical curves illustrating this are shown in Fig. 16.

§ (11) SPECIFIC HEAT OF GASES by the "METHOD of MIXTURES."—When defining the specific heat of a gas it is necessary to specify the conditions under which the heating takes place, since the change of volume with the rise of temperature is considerable under constant pressure, and the thermal equivalent of the external work done during expansion is a large fraction of the whole heat supplied during the change of temperature. Hence in the case of a gas it is customary to speak of two specific heats: (1) at constant volume, and (2) at constant pressure.

The earliest investigators to study the specific heat of gases were Lavoisier and La

---

**Fig. 15.** A nickel-lined bomb of iron 31 ft long. In weight, \( K, K' \), two constant discs soldered to bomb and to nickel surrounding vessel \( B \), quartz crucible.

**Fig. 16.** Curve A, pressure of gas = 100 lb. per sq. inch; curve B, pressure of gas = 250 lb. per sq. inch; curve C, pressure of gas = 500 lb. per sq. inch.

A few typical curves illustrating this are shown in Fig. 16.

**Table 1.** Specific heat of gases.
The term A corresponds to the heat conducted through the connecting pipe from the heater to the calorimeter, and B to the heat loss by radiation, etc., from the calorimeter. Each of these terms corresponded to about 5 per cent of the total energy supplied by the gas per minute. Regnault measured the constant A and B by noting the rate of rise of temperature of the calorimeter before and after the gas had passed through it. Swann 1 has pointed out that an error arises in assuming that the heat conducted through the pipe is the same when gas is flowing as when no gas is flowing; in fact the hot gas keeps up the temperature of the pipe in the vicinity of the heater and reduces the temperature gradient. The result is that less heat is conducted from the heater into the pipe when the gas flows through than when no gas is flowing. Of course a great deal of heat is conducted by the pipe into the calorimeter when the gas is flowing, but the greater part of this comes from the gas itself. The fact that the average temperature of the pipe is higher when the gas is flowing also results in a greater radiation loss from the pipe. The error acts in the same direction as the other.

Swann made some experiments to verify the above suggestion, and by attaching thermocouples to a metallic tube he showed that this gradient was affected by the flow along it and the results were of the magnitude required to account for the difference between his results and those of Regnault.

In Regnault's time there was a lack of knowledge concerning the variation of the specific heat of water with temperature, which, together with uncertainty as to the absolute scale of temperature, might also cause an error of 1 per cent in his results.

§ (15) VARIATION OF SPECIFIC HEAT WITH TEMPERATURE AND PRESSURE (OVER MODERATE RANGES).—Regnault's observations cover the temperature interval from -30° to 210° and pressures from 1 to 12 atmospheres. He found that the specific heat of the gases, air, oxygen, and hydrogen were independent both of the temperature and the pressure within the limits of the observations.

The specific heat of CO₂ on the other hand, showed a well-marked increase with rising temperature. Regnault's work was repeated by Wiedemann, who confirmed his results.

Witkowski investigated the specific heat of air at low temperatures from +100° to -170°, and found that the specific heat was independent of the temperature but increased with pressure. He worked up to a maximum of 70 atmospheres. The variations with pressure increased as the temperature was lowered.

The method of mixtures is not suitable for the accurate determination of the pressure and temperature variation of the specific heat of a gas.

More recent work by observers employing the electrical method has supplied data which supersede those obtained in the above-described investigations.

§ (16) SPECIFIC HEAT OF GASES AT HIGH TEMPERATURES. 5—Holborn and Austin, 3 and later Holborn and Henning, 4 have investigated the specific heat of gases up to 1200° C. Their method is identical in principle with that of Regnault's, but a special type of heater was necessary for bringing the gas to the high initial temperature. Their apparatus is shown diagrammatically in Figs. 17 and 18.

1 "Note on the Conduction of Heat along a Pipe through which Gas is flowing in the debation to Measurements of the Specific Heat of Tissues," Phil. Mag., Jan. 1873.
CALORIMETRY, METHOD OF MIXTURES

The calorimeter at calorimetric temperature even when heated to the highest point (800°) was made certain by tests with a constantan copper thermocouple.

Later experiments by Holborn and Henning were made by a similar method with a platinum heating tube which extended the temperature range to 1400°. The calorimeter necessarily gains some heat from the heating tube, and this gain, in the later experiments, was partly compensated by surrounding the calorimeter with a jacket maintained at a much lower temperature.

This compensation was found necessary at high temperature in order to prevent an excessively rapid rise of temperature of the calorimeter; but although it reduces the apparent magnitude of the correction required, it does not diminish the actual amount of heat transferred and does not reduce the uncertainty of the correction. The magnitude of the effect at high temperatures may be judged from the fact that it was found necessary, in the experiments at 1400°, to maintain the jacket at as low a temperature as 40° by passing a stream of cooling water through it in order to prevent the calorimeter rising above 110° when no gas was passing. Under such conditions the calorimetric corrections became so uncertain that the probability of systematic errors must increase considerably with rise of temperature.

The rate of increase of the mean specific heat of nitrogen at atmospheric pressure between 840° and 1340° C., shown by the later experiments, was about double that found in the earlier series. Both series of experiments could be represented within the limits of probable error by the linear formula

$$S_{at} = 2350(1 + 0.000045).$$

It appears probable, however, that the value of the specific heat at 0° C., given by the formula is too low and that in the case of nitrogen the rate of increase is not uniform, but increases with rise of temperature to some extent.

(iii.) Possible Sources of Error.—Since the temperature of the hot gases was determined by a thermocouple near the entrance to the calorimeter, and the time of flow of the gas was only three minutes, there appears to be some doubt whether the couple gave the true mean temperature of the inflowing gas, and also whether the loss by radiation from the couple was properly corrected for. The value of the mean specific heat of air over the range 150° to 270° C. by Holborn and Henning was 0.2315. This is about 6 per cent smaller than the probable value over this range. The rate of increase shown by the experiments was within the limits of probable accuracy of the work.

§ (17) SPECIFIC HEAT OF STEAM.—Regnault's value, 0.475 for the specific heat of steam at atmospheric pressure over the range 125 to 225° C. was obtained by taking the difference
between the total heat of steam, superheated in these temperatures, as observed by condensing the steam in a calorimeter. Since the difference, corresponding to 100° superheat, is only \( \sqrt[3]{3} \) of the total heat measured in either case, it is evident that the method might give rise to large errors. For this reason many writers have preferred to deduce the specific heat of steam theoretically in various ways from Regnault's value of the rate of change of the total heat of saturated steam, namely, 0-305 cal. per 1° C., which, as Callendar has pointed out, is subject to some source of error in an aggregated form. Thus Zinner gives \( S = 0.558 \); Perry, \( S = 0.500 \) at 0° C. to 0-364 at 210° C; Grindley, 0-387 at 100° C. to 0-005 at 100° C.

A direct measurement of the specific heat of steam by Brickworth, employing the continuous electric method devised by Callendar, gave \( S = 0.484 \) at 100° C. Subsidiary experiments by Callendar in conjunction with Professor Nicholson, by the throttling calorimeter method, enabled the variation of the specific heat with pressure to be calculated. These gave the formula

\[
S = 0.478 + 0.0242p \left( \frac{173}{p} \right),
\]

where \( p \) is the pressure in atmospheres. The approximate constancy of the limiting value 0-478 of the specific heat at zero pressure over the range 0 to 200° C. was verified by calculating the corresponding values of the saturation pressure, which were found to agree accurately with Regnault's observations over the whole range. The theory was also verified by a measurement of the ratio of the specific heats of steam by Makower, which gave values 1-303 to 1-301, agreeing closely with that deduced by Callendar.

The experiments of Lorentz and Knoblauch and Jacob and Lindo afforded a remarkable verification of the theory of the variation of the specific heat with pressure. They found the specific heat at 1 atmosphere to be practically constant over the range 100° to 300°, but their values, namely, 0-465, is decidedly lower than Regnault's.

Holborn and Hunning in their experiments on the specific heat of steam at atmospheric pressure, improved Regnault's method by employing an oil calorimeter at 110° C so as to avoid condensing the steam in the calorimeter. They determined the ratio of the specific heat of steam to that of air by passing currents of air and steam in succession through the apparatus under similar conditions, and obtained the following values of the ratio for different intervals of temperature:

<table>
<thead>
<tr>
<th>Temperature Interval</th>
<th>Ratio/Steam. Air</th>
</tr>
</thead>
<tbody>
<tr>
<td>100-370°</td>
<td>1-908</td>
</tr>
<tr>
<td>110-140</td>
<td>1-978</td>
</tr>
<tr>
<td>110-330</td>
<td>1-940</td>
</tr>
<tr>
<td>110-820</td>
<td>1-908</td>
</tr>
</tbody>
</table>

In their subsequent series with a platinum heating tube at higher temperatures they obtained the following ratios:

<table>
<thead>
<tr>
<th>Temperature Interval</th>
<th>Ratio/Steam. Air</th>
</tr>
</thead>
<tbody>
<tr>
<td>115-820°</td>
<td>1-900</td>
</tr>
<tr>
<td>115-1150</td>
<td>1-973</td>
</tr>
<tr>
<td>115-1254</td>
<td>2-003</td>
</tr>
</tbody>
</table>

The second series appears to make the ratio about 5 per cent lower at 110-370° than the first, which suggests the possibility of constant errors depending on the type of apparatus employed or on the velocity of the gas current. The experiments of Callendar and Swan would make the ratio 2-56 at 100° C. This is higher than any of the values obtained by Holborn and Hunning at 140° C.

Holborn and Hunning point out that their results at 140° C. cannot be reconciled in the case of steam and CO₂ with any of the results of expansion methods. They are 6 per cent to 13 per cent lower than Langen's, which are among the lowest. But, having regard to the fact that the constant-pressure method which they employed appears to give results so much lower than Joly's or Callendar's methods at ordinary temperatures, and that the experimental difficulties increase so greatly at higher temperatures, it does not seem at all improbable that a considerable part of the discrepancy is to be attributed to systematic errors of the constant-pressure method.

§ (18) SPECIFIC HEAT OF CO₂—The specific heat of CO₂ is of great theoretical interest in view of the considerable increase shown at ordinary temperatures. The table below gives the results obtained by various observers:

<table>
<thead>
<tr>
<th>Temperature</th>
<th>Regnault</th>
<th>Wiedemann</th>
<th>Stearn</th>
<th>Holborn</th>
</tr>
</thead>
<tbody>
<tr>
<td>0°</td>
<td>0-1570</td>
<td>0-1552</td>
<td>0-1573</td>
<td>0-2082</td>
</tr>
<tr>
<td>100</td>
<td>0-2145</td>
<td>0-2160</td>
<td>0-2133</td>
<td>0-2184</td>
</tr>
<tr>
<td>Increase</td>
<td>0-0575</td>
<td>0-0617</td>
<td>0-0260</td>
<td>0-0133</td>
</tr>
</tbody>
</table>

It may also be remarked that the variation of specific heat with density observed by Joly agrees very closely with that calculated by Callendar from the experiments of Joly and Thomson on the cooling effect on expansion.

CALORIMETRY, QUANTUM THEORY

THE VARIATION OF SPECIFIC HEAT WITH TEMPERATURE

§ (1) THE VARIATION OF ATOMIC HEAT.—
The discovery by Dulong and Petit in 1810 of the empirical law, that the product of the atomic weight and the specific heat is approximately the same for all elements, proved to be of the greatest practical utility to chemists when assigning atomic weight values to newly discovered elements; and further, the simplicity of the law directed attention to the possibility of arriving at it from theoretical considerations of conceivable atomic structures constituting a solid.

The mean value for the constant was determined by Bogmull as 6.38 with extremes of 5.76 and 5.7. According to the kinetic theory of matter it is easy to see why a relationship of the form discovered by Dulong and Petit should exist. We suppose that the atoms are bound together by interatomic forces tending to bring them to positions of equilibrium about which they oscillate; then in this case the total energy of an atom is half-potential and half-kinetic; for the principle of equipartition of energy is assumed to be valid.

Now in the case of a monatomic gas the energy is all kinetic, and proportional to the absolute temperature. Therefore the atomic heat should be half as great in the gaseous state as the solid state. The kinetic energy of a gramme molecule of a monatomic gas is 3/2RT, where R is the gas constant which has the value 1.085. Hence, on the supposition that a monatomic solid body is built up of atoms each with 3 degrees of freedom, the energy constant is 3/2T, and from this the atomic heat at constant volume is obtained by differentiation with respect to T giving for the atomic specific heat the value 1/2 or 0.505.

It might be remarked in passing that the above equation, according to Boltzmann, is applicable to the case of crystals which have at the points of their space-lattice molecules of any degree of complexity, provided that the internal forces acting on each atom are proportional to the distance of the latter from its equilibrium position, or more generally are linear functions of the change of its co-ordinates.

Hence the Dulong and Petit generalisation is consistent with the atomic theory of matter and the equipartition theory of energy.

For nearly a century, however, the exceptions to the law—carbon, boron, and silicon—proved to be an enigma which defied solution. As far back as 1872 Dewar and Weber, working independently, showed that as the temperature increased the specific heat of carbon, whether as diamond or as graphite, continued to increase. Weber concluded that the specific heat of diamond is tripled when the temperature is raised from 0° to 200°.

Dewar's experiments showed that the specific heat of carbon between 30° C. and the boiling-point of zinc (918° C.) was 0.32.

Some three years later Weber published results of further experiments, and proved that from 600° C. upwards the specific heat of carbon ceased to vary with increase of temperature and became comparable with that of other elements. Further, the difference between the specific heat of different modifications disappeared. By plotting his results

Weber showed that the specific heat-temperature curve was of the form of an old English j. He found a point of inflection for diamond at about 600° C., and that for graphite 0° C.

Recent researches have shown that the curve obtained by Weber is typical of all materials when the range of temperaturc investigated is sufficiently large.

By his development of the technique of low temperature research Dewar was able to

pursue the subject to still lower temperatures, and the results for carbon obtained up to 1012 are shown graphically in Fig. 1. More recent research by various investigators employing the electrical method has shown that the general form of the atomic heat temperature curve closely resembles the curve of magnetisation of a ferromagnetic substance under a steadily increasing magnetic force, with its gradual beginning, its subsequent rapid rise, and its final asymptotic approach to a limiting value. A four typical curves are shown in Fig. 2, the CΛ curve being obtained by calculation from C0 and the value of C−C0.

The above comparison of the frequencies shows that the values obtained from the specific heat equations are in fair agreement with those calculated from the elastic constants.

§ (4) APPLIcATION OF DEBYE'S AND EINSTEIN'S FORMULAE TO THE NON-METALS.— Pure metals afford the most reliable data for testing heat theories, but comparisons with the available experimental data for complex substances such as crystalline salts (NaCl, KCl, KBr, AgCl) and diamond are of great theoretical interest.

One difficulty in making such comparisons is uncertainty in the value of $C_p - C_v$ owing to the lack of data concerning the elastic constants. As data were not available for calculating $C_p - C_v$ from the thermodynamical relationship,

$$ C_p - C_v = \frac{\text{const}}{\rho} $$

Nornst and Lindemann \(^1\) obtained approximate values for $C_p - C_v$ by a different procedure.

**Note.** $C_v$ was obtained by calculation from the formulae and the calculated value of $C_p - C_v$ added.

It will be observed that, generally, near the boiling-point of liquid hydrogen, about 30° abs., Einstein's formula gives values which are too low; from Nornst and Lindemann's the values are too high; while Debye's formula gives values which are in fair agreement for Al, Ag, Zn, and Pb, and, in the case of other metals, it agrees with the experimental values better than either Einstein's or Nornst and Lindemann's. At liquid air temperatures all three formulae give values which are too high.

It is of last little use to calculate the appropriate values of $\nu$ from the elastic constants of the metals, since these constants are considerably influenced by the nature of the previous heat treatment and of the temperature. But it might be remarked that the values calculated from the elastic constants are in accordance with those required by the atomic heat results as shown by the data in Table II.

---

\(^{1}\) *La Théorie du rayonnement et les quantas*, 1912, p. 265.
of expansion is proportional to the atomic heat, and obtained the approximate relationship
\[ \alpha - \alpha_0 = C_0TA, \]
where \( \alpha \) is a constant characteristic of the substance which can be deduced from measurements of the compressibility and coefficient of expansion made at one temperature.

It is possible to test the validity of this formula by comparing the data obtained from it with those given by the thermodynamical equation in the case of the metals Al, Ag, Zn, and Cu (see Table III).

Nernst tested the formulae of Nernst and Lindemann and of Debye on the data for diamond, and Table IV. summarises the comparison.

It will be observed that Debye's formula was an approximate representation of the experimental results. The Nernst and Duvac formula gives values which are a low between 88° and 92° abs. In the case of Debye the differences across the visible part of the experiment, the general and being the Debye formula to give values which are too high at low temperatures and too small at high temperatures. In fact a decrease of atomic heat with decreasing temperature is more rapid than that given by Debye's formula. Ewald made experiments on the mean atomic heat of diamond between 83°-8° and 194°-0° abs, and found the line 0-2110, so that the total energy difference between these temperatures is 35 calories; the value calculated from Debye's formula is 25.34. Kord, employing a copper calorimeter described in "Calorimetry, Electrical Methods," § (13), found a mean atomic heat of diamond between 32° and 270° to be 0.56, corresponding to an energy difference of 05.8. Debye's formula gives 61.9 calories for this interval.

### Polyatomic Substances

- The metals and diamond are regarded as monatomic structures, whilst the molecules of graphite and sulphur appear to be compounds of several atoms since the atomic heat curve is for these much less abruptly curved towards the temperature axis.

Nernst has attempted to apply the formula of Debye and Einstein to polyatomic substances such as KC1, NaCl, etc. He assumes the heat vibration to be of two types: first, the vibration of the molecules as a whole in exactly the same way as the atoms of a monatomic body; and, second, the vibration of each atom about its position of rest. The vibrations of the atoms are interpreted as giving rise to the "Reststrahlen" discovered by Rubens. Since at low temperatures the vibrations of the atoms become much more regular, and accordingly the absorption bands narrower and more pronounced, it is assumed that Einstein's function applies to the atomic vibrations.

Hence for the representation of the atomic heat of the salts the expression is
\[ 2G_{\text{at}} = \frac{1}{2} \left( \frac{\beta n^2}{T} \right) + \frac{1}{2} \left( \frac{\beta a^2}{T} \right), \]
in which \( \beta_n, \beta_a \) are the functions of Debye and Einstein respectively, \( r_1 \) the frequency calculated from the melting-point, and \( r_2 \) that found by Rubens by means of the optical method, since these salts show one very sharp infra-red absorption band.

For details of the comparison with experiment, reference should be made to the original papers already referred to in the text.

### Calorimetry, Quantum Theory

- The 17°:-"The quantity of heat required to raise one gramme of water through 1° C. at 15° C. See "Thermodynamics," § (2); "Heat, Mechanical Equivalent," § (6).

The 17°-5:-For some purposes the range from 16° C. to 20° C. is taken and the caloric defined at 17°-5.

- Grammae.-One-hundredth part of the heat required to warm one gramme of water from the melting-point to the boiling-point at a pressure of one atmosphere. See also "Thermodynamics," § (2); "Heat, Mechanical Equivalent," § (6).

- Pound.-A British unit of heat, being one-hundredth of the amount of heat required to raise one pound of water from the

Lindemann, "Physik Zeitschr.," 1910, 5, 480. Using the hypothesis that the melting-point is determined by the fact that at this temperature the amplitudes of the vibrations of the atoms around their positions of rest become commensurate with the atomic distances.
in the pressure this is equivalent to a pressure time record. The advantage of the method lies in the fact that the inertia of the moving part of the recorder, the beam of cathode rays, is negligible.

The apparatus consists of two parts: (1) the pressure vessel, and (2) the cathode ray oscillograph.

The pressure vessel is shown in Fig. 1. It consisted in Dr. Keys' experiments of a brass vessel AB, about 1 in. in diameter and \( \frac{1}{2} \) in. deep closed by a \( \frac{1}{2} \) in. steel plate HK, held down by 12 bolts. The walls of the vessel were \( \frac{1}{2} \) in. thick. A sparking plug L and a tap

![Fig. 1](image_url)

N are fitted in the steel cover. DE is a thin lead plate electrically connected to a copper wire which passes through an insulating plug C in the side of the vessel.

Half of the tourmaline crystals, about 1 cm. in thickness, are attached by a little wax to the bottom of the vessel, the other half are attached similarly to a steel plate H. The lead plate DE separates these two sets of crystals, which are so arranged that all the positive faces are in contact with the lead plate. There are 5 or 6 crystals in each layer, the area of each crystal being about 12 sq. cm. HI is fixed by steel screws to the bottom of the vessel. The lower part of the vessel is filled with vaseline to delay the transfer to the crystals of the heat generated by the explosion.

When pressure is applied above HI, DE becomes positively charged and the amount of the charge is proportional to the pressure. The insulated wire EGF conveys the charge to the condenser of the oscillograph. This is shown in Fig. 2. The cathode rays are generated by the fine tungsten filament F.
which is heated to incandescence by an 8-volt accumulator. The cathode ray tube CC is mounted in a brass sleeve BB which is soldered into a brass cylinder CC—the axis of this cylinder is at right angles to the paper. The rays enter the sleeve BB through a small hole O, pass between the plates MN of a condenser and then between the poles WW of the electromagnet and fall on a photographic plate X in the cylinder CC. The plate slides in a rectangular box within the cylinder and can be moved from outside. A window Y in the cylinder CC closed by a screen of willinite allows visual observations to be made when the plate is drawn aside and thus facilitates adjustment. The electromagnet is excited by an alternating current of known frequency, thus the time scale is fixed. LL is a brass guard tube ⅛ in. in diameter. This guard tube and one of the condenser plates N are connected to earth and to one pole of a direct current generator supplying a constant potential difference of from 3000 to 5000 volts. The other pole of the generator is connected through a special double-acting key S to the tungsten filament; the key also serves to fire the explosive mixture. The second plate M of the condenser is connected to the lead plate of the pressure vessel. On depressing the key S the cathode potential supplied by the direct current generator is first communicated to the tube; a further motion of the key detaches the charge. The cathode rays are deviated in a direction at right angles to the paper by the magnetic field, and until the charge is fired traces a short vertical line on the photographic plate. The electrification of the condenser plate M due to the pressure produces a deflexion of the rays in the plane of the paper and thus the time-pressure curve is traced on the plate. The displacement of the spot depends on (1) the cathode potential and (2) the potential difference produced by the charge between the plates of the condenser MN; the apparatus requires calibrating for these. For the method of doing this reference should be made to Dr. Keys' paper.

Figs. 3, 4, 5, 6, taken by permission from his paper, give the results of some of his experiments; the effect of the addition of air in slowing down the explosion of H₂ and O shown in Fig. 3 is very marked. With no air (curve I) the maximum pressure of about 220 lbs. per sq. in. is reached in less than 0.0083 seconds. With some 60 per cent of air in the mixture (curve III) the maximum pressure is reduced to less than 60 per cent of its former value and the rise continues for about 0.003 seconds, or some fifteen times as long as previously.

The curve A, Fig. 5, is a time-pressure curve for the explosion of gun-cotton under water; it gives the direct wave, while curve B is due to the wave reflected from the bottom. Again in Fig. 6, the effect of altering the distance of the charge from the pressure vessel is shown.

COAL CALORIMETER

Various forms of apparatus have been devised for determining the calorific value of coal. In practically all the selected sample of coal is burned in oxygen; the products of combustion are passed into a known quantity of water at a known temperature, and the rise of temperature is measured.

Fig. 1 is an illustration of the Rosenthal calorimeter as manufactured by the Cambridge and Paul Instrument Company. The instrument consists of two parts, the calorimeter proper containing the water and the combustion chamber in which the sample is burned.

The combustion chamber is formed of a glass lamp chimney closed at the top and bottom by metal clamping plates, separated from the glass by rubber washers and held together by clamping screws on three uprights fixed to the lower plate; the wires connected to the electric ignition arrangement pass through the upper plate and are a tube for the supply of oxygen. The whole chamber is immersed in the water of the calorimeter. An aperture in the plate is closed by a ball valve through which the products of combustion can issue into the water, but which prevents the entry of water into the combustion chamber. On the completion of the experiment the valve is raised, allowing some water to enter; this is afterwards forced out by the oxygen and mixed with the rest of the water, thus ensuring that the calorimeter and its contents are brought to one temperature. To reduce the radiation losses the whole

DYNAMICAL SIMILARITY, THE PRINCIPLES OF 1

I. GENERAL PRINCIPLES

§ (1) GENERAL. Scientific research concerns itself with the discovery and expressions of laws as exact relations between physical quantities of different kinds. Involved in the expression for the magnitude of any such quantity are two conceptions—the nature or kind of unit in terms of which it is represented, and the magnitude or number of times the unit occurs in the physical quantity considered. Thus, in the statement that the earth's diameter is 8000 miles, there is implied the nature of the fundamental unit (mile) in terms of which the diameter is measured, and the number (8000) of these units which are present in the physical quantity. If the whole function of scientific research consisted in a comparison of quantities of the same kind then the desiderata in the selection of a unit could be easily defined, and would merely involve such considerations as definiteness, non-ambiguity to scalar change, and capability of accurate comparison with the quantities to be expressed in terms of it. Since, however, research in its wider sweep investigates and expresses relations between quantities of such different kinds as forces, temperatures, magnetic moments, etc., it follows that, for simplicity and clarity, not merely must these units be selected to satisfy the above requirements, but only such units must be accepted as express all the quantities concerned in the simplest manner possible in terms of the minimum number of independent units.
§ (2) SIAM UNITS.—For mere geometrical relations which are expressions of space truths involving lengths, areas, and volumes, it is clear that only one independent unit is required, which, apart from convenience and form, may arbitrarily be selected as the unit of length of area, or of volume. If, for example, the unit of volume, be taken as the standard dimension, then since the product of three lengths provides a volume, the dimension of length would be \( V^1 \), and that of area, \( V^2 \). It is obvious that the clearest and, to us, the simplest expressions will be obtained by choosing as our standard unit a length \( L \), giving us dimensions of area \( L^2 \) and volume \( L^3 \).

§ (3) KINETIC UNITS.—Passing to laws involving kinematic considerations it becomes at once clear that a new unit must be introduced to provide a measure of motion, a change in length with time; and once more the simplest mode of representation is arrived at by choosing a unit for speed or acceleration, and hence expressing the fundamental idea of time in a more or less complicated form, but by selecting a unit for time, say \( T \). Speeds and accelerations are then at once seen to have the dimensions \( L/T \) and \( L/T^2 \) respectively.

§ (4) DYNAMIC UNITS.—But the two units of length and time are not in themselves sufficient to specify quantities which arise immediately we enter the domain of dynamics. At the basis of the system of analysis lies the fundamental idea of force and its representation in terms of mass and acceleration. Before a full expression for the dimensions of dynamical quantities can therefore be set out, either a new unit of force must be introduced in terms of which, by Newton’s Second Law, the dimension of mass could be expressed, or a unit of mass must be presumed and the dimensions of dynamical quantities derived from it. Once more for reasons of simplicity we choose the latter. Accordingly, writing \( M \) as the dimension of the mass unit, the following table of quantities and their dimensional representation may be drawn up:

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Dimension</th>
</tr>

<tr>
<td>Density ( M/L^3 )</td>
<td>( M/L^3 )</td>
</tr>
</tbody>
</table>

§ (5) HOMOGENEITY OF DIMENSIONS IN A PHYSICAL EQUATION.—Since the mathematical formulation of any physical law is a statement of equality or relationship between physical quantities necessarily of like nature, since indeed a force cannot be added to a mass but only to another force, now a temperature equated to an electric charge but only to another temperature, it follows that all the terms in any equation having a physical significance must necessarily have identical dimensions. In the expression for the velocity acquired by a particle in macro dropped from rest under gravity, for example,

\[ v^2 = 2gh \]

the dimensions of the left-hand side are \( (LT)^{-2} = LT^{-2} \), while on the right-hand side they are \( LT^2 \times L = LT^3 \), the constant being of course non-dimensional.

This fundamental principle serves not merely as a check on the intelligibility of any formula derived either on experimental or on theoretical grounds, but can be turned to much greater advantage by providing a priori information regarding the form which the result of any investigation ought to take. It will become apparent as the subject develops that there exists here a potent weapon for a preliminary analysis of any proposed problem. Particularly is this true in the realms of physics and engineering.

The method that may be adopted will become apparent from a few simple dynamical illustrations. Let us assume that the time of oscillation of a pendulum in vacuo is the problem for analysis, in order to determine how the period depends on the length of the suspension, the mass of the pendulum bob, and the value of gravity. Without a preliminary analysis along the present lines, and failing a complete mathematical investigation, it would appear at first sight that a complete experimental study of the problem would involve a threefold series of experiments corresponding in variations in length of suspension, mass of bob, and gravity. Consider the physical factors upon which the period might possibly be dependent. They are, mass of bob \( m \), length of suspension \( l \), value of gravity \( g \), the form of attachment possibly, and the shape of the bob. The last two factors may or may not enter, but in any case it is not clear how they can be directly introduced by any single convenient symbol. Let us assume then that in all the experiments these are invariant, and therefore from our a priori knowledge we affirm

\[ t = f(m, l, g) \]

where \( f \) represents the function which requires determination. Let us suppose this expanded in a power series in \( m, l, \) and \( g \), so that

\[ t = AMnPg^q \]

where the terms \( A \) are constants independent of \( m, l, \) and \( g \) and functions only of the shape of the bob. This much, however, we can affirm, that each term in the expression must of necessity represent a quantity of the nature of time, and must therefore have the same dimensions as \( t \).
Now the dimensions of
\[m^2 \cdot s^2 \text{ m}^3 \text{ kg}^{-2} \text{ N}^{-2} \cdot \text{ m} = M^0 L^1 T^{-2} \cdot \text{ kg}^0 \text{ s}^2 \cdot \text{ m}^1 \]
and equating these to the dimensions of \( t \) we find
\[x = 0, \quad \sqrt{y} = 0, \quad 2z = 1.\]
Thus,
\[t = \sqrt{\frac{l}{g}},\]
where \( c \) is some unknown constant. A preliminary analysis of the problem has now reduced the necessity for a thorough set of experiments to one experiment, and one only, to determine the value of \( c \). We have shown in fact that there are not in reality three variables \( x, y, \) and \( z \) in the problem, but one single variable \( t \sqrt{g/y} \) which groups together a whole set of experiments as essentially of the same type. What then is the common principle that runs through the problems of the times of oscillations of pendulums of different lengths under different values of \( g \), that it should be possible to group them together? What is the physical or dynamical significance of this grouping?

§ (6) DYNAMICAL SIMILARITY.—In the foregoing analysis we might equally well have taken \( t \) to represent the time taken for the pendulum to swing out to a given angle \( \alpha \), then \( t = \sqrt{\frac{l}{g}} \), where \( t \) is now constant, when \( \alpha \) is constant. It follows at once that if two pendulums of lengths \( l_1 \) and \( l_2 \) at different points on the earth's surface such that gravity is \( g_1 \) and \( g_2 \) respectively, are allowed to swing, then at all times \( t_1 \) and \( t_2 \) such that \( \sqrt{g_1/l_1} = \sqrt{g_2/l_2} \), the pendulums will be displaced by equal angles. A series of photographs on plates of the same size taken of all such pendulums at any such series of corresponding times will be identical. The geometrical configuration for all such corresponding times are similar. Systems in motion which can thus be grouped together quite generally as passing through geometrically identical phases for equal values of a non-dimensional grouping of corresponding quantities—in the above case for equal values evidently of \( t \sqrt{g/y} \)—are said to possess dynamical similarity.

§ (7) APPLICATION TO PARTICLE DYNAMICS. Consider a further example from particle dynamics. A particle of unit mass is projected with velocity \( V \) in a field of force such that the acceleration at any point \( (x, y) \) is \( A(x, y) \), what information relative to the distance traversed after any time is supplied by the method of dimensions? For this purpose let us write \( A(x, y) = a \cdot a(x, y) \), where \( a \) is the actual acceleration at some special point, say the point of projection and \( a(x, y) \) is the function giving, as it were, the law of distribution of acceleration. Under these circumstances since both \( A(x, y) \) and \( a \) are accelerations, \( a(x, y) \) must have zero dimensions. Restricting ourselves to a series of problems for which this law of distribution remains unaltered although the magnitude of the acceleration at any point may vary—i.e., the function \( a \) remains unaffected, but \( a \) varies from problem to problem—we may say that \( S \), the distance traversed after any time, is a function of \( V \), the velocity of projection, \( a \) the measure of the acceleration, and \( t \) the time, i.e.,

\[ S = f(V, a, t) \]

Willing as before

\[ S = V A(V^2 a^2), \]

and equating dimensions, we find

(1) \[ 1 + x = y; \quad x = 1 - y, \]

(2) \[ 0 = x + 2y - z, \quad z = 1 + y, \]

\[ S = V A(V^2 a^2) = V A \left( \frac{at}{V} \right). \]

Since \( y \) is quite arbitrary and may have any value whatsoever while still satisfying the dimensional conditions, this implies that

\[ S = V \left[ 1 + \frac{at}{V} \right]. \]

§ (8) NON - DIMENSIONAL VARIABLES. It should be particularly remarked that the problem has reduced itself to the determination of the relation between two non-dimensional groups of terms \( S/V \) and \( at/V \), the functional relation between these depending purely on the geometrical conditions of the problem and in no wise on the dynamical principles involved. In the same way the oscillating pendulum was reduced to the determination of the value of the single non-dimensional group of terms \( t^2 g/y \) as a numerical.

In general, it will be seen that for dynamical problems, at most three equations can be obtained from the dimensions of mass, length, and time, although there may be less if any of these be absent. In general, therefore, if there are \( n \) quantities upon which the whole functional relation depends, the number of these quantities can be expressed in terms of the others, and there will be left a relation between \( n - 3 \) non-dimensional groups of terms.

§ (9) APPLICATION TO PLANETARY THEORY. As a further example of a slightly different
DYNAMICAL SIMILARITY, THE PRINCIPLES OF

nature showing the insight here provided into a problem without actually analysing in detail the dynamical conditions, consider what may be deduced from Newton's Gravitational Law, regarding the periodic times of planets.

The attractive force between two planets of masses \( m_1 \) and \( m_2 \) at distance \( r \) apart is, according to Newton,

\[ F = \frac{G m_1 m_2}{r^2}, \]

Accordingly the dimensions \( [F] \) of a gravitational constant, are

\[ [F] = [E] \times \left[ \frac{\text{kgm}^2}{\text{sec}^2} \right] \times \left[ \frac{\text{m}}{\text{kgm}} \right] = \left[ \frac{\text{m} \cdot \text{kg}}{\text{sec}^2} \right] = \text{MIL}^{-2}. \]

If \( d \) be the major axis of the orbit of a planet of mass \( E \) moving round a central sun \( S \), then \( \tau \), the periodic time of the motion, can depend only on \( d, E, S, \) and \( k \),

\[ \tau = \frac{2\pi}{k} \left[ \frac{\text{kgm}}{E} \right] \]

Hence equating like dimensions

\[ x + 3 = 0, \quad y + 2 = 0, \quad -2u = 1, \quad v = 0, \quad w = -\frac{1}{2}, \quad \tau = \frac{2\pi}{k} \left[ \frac{\text{kgm}}{E} \right] \]

\[ \text{Thus, } \quad \frac{d}{\sqrt{2E}} = \frac{\phi}{k}. \]

From which Kepler's Third Planetary Law follows immediately, that the square of the periodic time is proportional to the cube of the major axis of the orbit.

But it is not in the field of pure dynamics that the method here developed receives its most fruitful applications. In almost all branches of physics a preliminary analysis of any problem that requires investigation, provides an insight into the main factors which are at work, and thus generally indicates the direction in which the research should be developed.

In aerodynamics and aero-engineering, for example, we are concerned with the laws of air resistance to bodies of various shapes, and with the mass of which heated bodies such as rockets, etc., will cool in a current of air. Especially during recent years have innumerable problems of this nature arisen which, because of the complex and intricate mathematical expressions for the physical laws involved, have not yet yielded to theoretical analysis. On the experimental side, however, a considerable amount of work has been carried out, frequently without according the results the full interpretation that might have been given them from the present standpoint. It will become evident that only by an analysis along the lines of DYNAMICAL SIMILARITY one can find the full and most reasonable interpretation for any such work to be obtained.

§ (10) APPLICATION TO THE MOTION OF FLUIDS. — In dealing with the motion of liquids it is necessary, in the first instance, to account in detail the defining properties of that medium, quite apart from any theories regarding the molecular constitution of the fluid—liquid or gas. In the selection of such definitive properties, then, we are only concerned with those that are called into action under the circumstances contemplated in the problem. It suffices accordingly to define any fluid as dense, viscous, and elastic in the first instance, omitting for the moment those properties that become evident on the application of heat. Other properties may make themselves apparent in special circumstances, whilst even some of those enumerated above may in other circumstances become of little consequence.

If we are concerned, for example, with the dripping of liquid from a tube, the elastic properties of the fluid may be omitted, its viscosity may even play only a minor part, while surface tension enters as an important factor since the problem is clearly affected by the nature of the conditions at the surface between the liquid and the air.

As far as all these properties are concerned it is possible to express their measure, as in the case of purely dynamical quantitates, in terms of the three fundamental units of mass, length, and time, from the mere definition of the physical properties they are intended to represent.

Viscosity, for example, is introduced through the coefficient of viscosity \( \mu \) defined by:

\[ \mu = \text{viscous force per unit area per unit velocity gradient} \]

from which it follows that the dimensions of \( \mu \) are

\[ [\mu] = \left[ \frac{\text{Force}}{\text{Area}} \right] \times \left[ \frac{\text{Velocity gradient}}{\text{Length}} \right] \]

As already indicated, density \( \rho \) has dimensions \( \text{ML}^{-3} \). Surface tension \( \sigma \), defined as a force per unit length of a curve, has therefore dimensions

\[ [\sigma] = \left[ \frac{\text{Force}}{\text{Length}} \right] = \text{ML}^{-1}. \]

As already indicated, density \( \rho \) has dimensions \( \text{ML}^{-3} \). Surface tension \( \sigma \), defined as a force per unit length of a curve, has therefore dimensions

\[ [\sigma] = \left[ \frac{\text{Force}}{\text{Length}} \right] = \text{ML}^{-1}. \]

\[ \sqrt{[\mu]} = \left[ \frac{\text{Force}}{\text{Area}} \right] \times \left[ \frac{\text{Velocity gradient}}{\text{Length}} \right] = \text{ML}^{-\frac{3}{2}} \]

\[ \sqrt{[\rho]} = \left[ \frac{\text{M}}{\text{L}^3} \right] \times \left[ \frac{\text{L}^{3/2}}{\text{L}} \right] = \text{ML}^{-1/2}. \]

\[ \sqrt{[\sigma]} = \left[ \frac{\text{M}}{\text{L}^3} \right] \times \left[ \frac{\text{L}^{3/2}}{\text{L}} \right] = \text{ML}^{-5/6}. \]
DYNAMICAL SIMILARITY. THE PRINCIPLES OF

Initial scrutiny of the question is concerned, those would appear to be the only properties of the fluid that ought to enter. On general grounds, moreover, we are aware that for slow vibrations viscosity plays a very minor part, and since the present instance the motion is essentially slow since the fluid is only dripping, viscosity might legitimately be omitted from the discussion, but whether or not this is justifiable is of course definitely a question of experiment. The only other factor that would enter there is the size and shape of the tube. Let the diameter be $d$, but the shape cannot be introduced by any definitive symbol.

Let the mass of each drop $M$ be presumed a function of $S$ the surface tension, $\rho$ the density, $g$ gravity, and $d$.

Taking as a typical term in the expansion of this function $A_0 g^2 d^2$, and writing it dimensionally, we find

$$M = (M_0 - A g^2 d^2) - (M_0 - A g^2 d^2) = \frac{S}{g}$$

The typical term is thus:

$$A_0 g^2 d^2 = \frac{S}{g}$$

From this simple analysis it can consequently be deduced that the problem under discussion must be regarded as the determination of the law of variation of the non-dimensional group $Mg/Sd$ with the non-dimensional group $S/\rho g d^2$, and that since the form of the approximately arbitrary function $\phi$ can depend on nothing but the shape of the tube, the curve obtained by plotting $Mg/Sd$ against $S/\rho g d^2$ will be characteristic of that shape of tube and quite independent of the actual values of $S$, $d$, $\rho$, etc. Actually, it has been found by experiment that the mass of the drops is proportional to $d$ the diameter of the tube (Clapeyron's Law). If we now therefore examine the function $(Sdg/p)(S/\rho g d^2)$, it is clear that unless the function $\phi$ be a more constant $M$ cannot possibly be proportional to $d$, and consequently on the basis of two sets of investigations during which $d$ alone is varied, while $S$, $\rho$, $g$, etc. are maintained constant, it can be deduced that when all the quantities are varied

$$M = \frac{A S d}{g}$$

where the constant $A$ may be determined from one experiment.

In the same way, if the drop of liquid be set in vibration, the frequency $n$ will depend on $g$, $\rho$, $d$, and $S$ as before, from which, noting that $A$ is $T^{-1}$, it can easily be shown that

$$n = \sqrt{\frac{S}{g^2 d^2}} F \left( \frac{S}{\rho g d^2} \right)$$

§ (12) VIBRATIONS OF A GRAVITATING LIQUID GLOBE.—A globe of liquid, such as a planet in a fluid state, is held together by its own gravity, and is set into a state of vibration by some external disturbance. What information regarding the frequency of vibration in any of its modes can be derived by the Dimensional Method?

The frequency will clearly depend on $\rho$ the density, $d$ the diameter of the sphere, and $k$ the gravitational constant, assuming that surface tension and viscosity are without influence on the question. Accordingly

$$n = f(\rho, d, k) = \Sigma A g^2 d^2$$

The dimensional expressions for each of the quantities $d$ and $k$ are known and have already been used. Inserting these it follows at once that $x = 1/2, y = 0$.

Hence $\rho \propto \sqrt{L}$. It appears the frequency is independent of the diameter of the sphere and proportional to the square root of the density.

§ (13) VELOCITY OF WAVES.—By a similar process of reasoning it is easy to establish the formula for the wave velocity in the case of heavy gravity waves in deep sea, $v^2 = gA$ where $A$ is the wave-length, and $v^2 = -\rho g$ for small surface-tension waves.

A clear insight into the principles of Similitude that lie at the basis of this method is best afforded by a general treatment of the motion of a viscous fluid, correlating many apparently diverse phenomena, and laying them clear as natural concomitants of the operation of the general principle of Dynamical Similarity.

§ (14) MOTION OF A BODY IN A VISCOUS FLUID.—Let it be supposed that a body or system of bodies of given geometrical shape, and size specified by the length $t$ of some portion of the system, is moving with velocity $V$ in a fluid of density $\rho$ and kinematic viscosity $\nu = \mu/\rho$, and for the moment it will be presumed that the fluid is inelastic. As a matter of actual experiment it is found that until the velocity approaches that of sound waves in the medium do its elastic properties make themselves apparent. Then the velocity $v$ at some point of the fluid, and particularly fixed with reference to the body may quite generally be written as

$$v = \phi(V, \rho, \nu, t)$$

while the slope $\theta$ of the stream line at that point is

$$\theta = \phi(V, \rho, \nu, t)$$

Applying the principle of Homogeneity of Dimensions and remembering that $\phi$, the
DYNAMICAL SIMILARITY, THE PRINCIPLES OF

shape, is of zero dimensions being a mere number, it is found that

\[ v = \sqrt{\frac{V}{\nu}} \]

\[ \theta = \sqrt{\frac{V}{\nu}} \]

The second equation indicates that the shape of the stream lines and the direction of motion at any time depend only on the value of the non-dimensional group \( Vi/\nu \), and not on the separate constituents of that group. The magnitude of the velocity likewise depends on \( Vi/\nu \) and on \( V \) alone. We see in fact that provided a system of bodies are all geometrically similar, their sizes being different, the systems of stream lines generated are likewise similar, provided \( Vi/\nu \) is maintained constant throughout the system.

§ (17) Reynolds’ Number.—As a matter of actual experiment Reynolds,¹ by a brilliant series of investigations, demonstrated that the whole process which takes place during the motion of a fluid does not depend alone on any of the single quantities \( V, L, \rho \), but on the group; moreover that for any given problem—in his case the flow of fluid through circular pipes—\( Vi/\nu \) is a critical variable, which when it attains a certain value corresponds to a more or less rapid change from one state of flow to another, from the steady so-called stream-line flow to the sinuous and turbulent state of eddy formation. Let us suppose then that eddying has originated, that is to say that the fluid on its passage past the obstacle forms in the neighbourhood of the sides of the latter a system of eddies which are shed periodically.

§ (18) Frequency of Eddy Formation.—Let \( f \) be the frequency of these eddles, then clearly it can only be a function of \( V, L, \rho \), and \( \rho \) apart from the geometrical shape of the obstacles.

\[ n = f(V, L, \rho) \]

Remembering that the dimension of \( n \) is \( T^{-1} \) and applying the method of this article, we easily find

\[ n = \sqrt{\frac{V}{\nu}} \]

indicating once more that if \( Vi/\nu \) is maintained constant for a series of similarly shaped bodies, for each system

\[ \frac{V}{\rho} \]

\[ \frac{V^2}{\rho} \]

\[ \frac{V^3}{\rho} \]

Hence for a given value of \( Vi/\nu \), and a given fluid so that \( \nu \) is also constant, the frequency is proportional to the square of the velocity or inversely as the square of the size.

§ (17) DYNAMICAL SIMILARITY IN THE MOTION OF A VISCOUS FLUID.—What this

¹ Phil. Trans. (1895; Collected Works, II, 51.

implies may be summarized by saying that if a series of bodies all of the same geometrical shape be moving in a system of fluids, viscous at \( \nu_1, \rho_1 \), with velocities \( V_1, \rho_1 \), . . . then provided \( Vi/\nu \) is maintained constant, photographs of the flow pattern taken on cinematographic films of the same size will all be identical, as far as the consecutive geometrical configurations of the stream lines and eddying systems are concerned.

The rates at which the processes unfold themselves will, however, be different, being in fact determined by the expressions for the frequency \( f \), but clearly if the photographs be compared at corresponding times as indicated above, the pictures will be identical. We see in fact that the condition, \( Vi/\nu \) constant, involves for geometrical similarity of boundaries, physical similarity in the motions.

This idea has been seized upon and used to great advantage in aerodynamical and naval architectural analysis, for, as will be immediately seen, it provides the basis for the analysis of full-scale problems in aeroplane, navalship, and naval construction, by means of tests on models.

§ (18) RELATION BETWEEN EXPERIMENTS ON MODEL AND ON FULL SCALE.—Such analysis, in general, centres itself round the question of how, from measurements of the forces originated during the motion of the model, to predict the corresponding forces that will be called into play during the motion of a full-scale machine or part.

The details of this will be given in another section ("Aerodynamics Scale-effect"),¹ but for the purposes of the present article we may note the main principles at work. If \( R \) : resistance of a body of dimension \( L \) in its motion through fluid of density \( \rho \) and viscosity \( \nu \) with velocity \( V \), we may say that \( R = \beta(V(\rho, \nu)) \) and applying again the method of the present article we easily determine \( \beta \) in the form

\[ R = \rho V^2 \text{d}(\frac{V}{\nu}) \]

§ (19) NON-DIMENSIONAL RESISTANCE COEFFICIENT.—Stating the law of resistance in the manner that has been followed in previous analysis as a relation between two non-dimensional groups of terms,

\[ \frac{R}{\rho V^2} = f(\frac{V}{\nu}) \]

indicating that the question of the forces resisting a body in its motion through a viscous fluid is most properly represented as a curve showing the variation of the "resistance coefficient" (non-dimensional) \( R/\rho V^2 \) as ordinate, against Reynolds’ non-dimensional number \( Vi/\nu \), as a base.

§ (20) CHARACTERISTIC CURVE.—Such a curve will be characteristic of that shape of

¹ See Vol. IV.
body, but will be absolutely independent of the scale of the problem and of the consistent set of units in terms of which the various factors are expressed. If therefore by experiment on a model of an airship, approached, or any portion of it, values of the resistance coefficient can be obtained for a sufficiently wide range of the single variable \(\frac{V}{a}\), the same resistance derivative will be valid for the full scale at the same value of \(\frac{V}{a}\). In actual practice it is extremely difficult, except in rare cases, to obtain a sufficiently wide range of this quantity, and methods of extrapolation supported by full-scale experiments have to be resorted to.  

Fortunately, extrapolation is greatly simplified in practice by the fact that for increasing values of \(\frac{V}{a}\), the resistance tends to increase steadily as the square of the speed, so that \(\frac{R}{a^2}\), and consequently \(f(\frac{V}{a})\), tends to become constant.

\[ f(\frac{V}{a}) \]

§ (21) FORCES DURING ACCELERATED MOTION.—In the above discussion we have merely considered the question of the forces called into play when the body is in steady motion. Can we derive from first principles any information regarding the nature of the resistance when the body, moving under an acceleration \(a\), say, passes through the velocity \(v\), without our having recourse to the complicated mathematics of fluid motion? Employing the same symbols as previously, but writing \(v\) as the velocity not of steady motion but of the body at the instant under consideration, and \(a\) its acceleration at that moment, then following the process already adopted we obtain as the expression for the resistance

\[ R = \rho a^2 f \left( \frac{v}{a}, 0 \right) \]

where in addition to the non-dimensional group \(\frac{V}{a}\) already obtained, there is now introduced the expression \(\rho a^2\) on which the additional resistance depends, not, as it noted, on the acceleration alone, but on the variation of this group.

\[ \frac{R}{a^2} = \rho a^2 f \left( \frac{v}{a}, 0 \right) \]

and

\[ \frac{R}{a^2} = \rho a^2 f \left( \frac{v}{a}, 0 \right) = \rho a^2 f \left[ f \left( \frac{v}{a}, 0 \right) + \frac{a}{a} f \left( \frac{v}{a}, 0 \right) + \ldots \right] \]

indicating that the additional force originated by the accelerated motion is equal to that required to give a mass of fluid \(\rho a^2\) an acceleration \(a\) of the body. But \(\rho a^2\) is proportional to the mass of the displaced fluid, and consequently it follows that for a given value of \(\rho a^2\), the effect of accelerating the motion is to give rise to an apparent increase in mass proportional to the mass of the fluid displaced.

Measurements of this so-called "virtual mass" are of importance in the stability of airships where the mass of fluid displaced is the same as the total weight of the ship, and where consequently the "virtual mass" may require a considerable magnitude. It may be remarked that for investigations of this nature the results would naturally be plotted showing the variation of the non-dimensional resistance coefficient \(R/\rho a^2\) either with \(\rho a^2\) for various values of \(a\) or conversely, and for a complete investigation the full range, zero to infinity, of \(\rho a^2\) must be covered.

§ (22) VIRTUAL MASS.—To determine more closely the effect this produces on the resistance, let \(R\) = resistance for steady motion at velocity \(v\), and \(R + \Delta R\) the resistance for an acceleration term \(\rho a^2\) small compared to unity, then

\[ R + \Delta R = \rho a^2 f \left( \frac{v}{a}, 0 \right) \]

for a full explanation of this, see "Aeronautics," Vol. IV.

\[ \text{DYNAMICAL SIMILARITY. THE PRINCIPLES OF} \]

\[ \text{Indicating that the additional force originated by the accelerated motion is equal to that required to give a mass of fluid } \rho a^2 f \left( \frac{v}{a}, 0 \right) \text{ the acceleration } a \text{ of the body. But } \rho a^2 \text{ is proportional to the mass of the displaced fluid, and consequently it follows that for a given value of } \rho a^2, \text{ the effect of accelerating the motion is to give rise to an apparent increase in mass proportional to the mass of the fluid displaced.} \]

\[ \text{Measurements of this so-called "virtual mass" are of importance in the stability of } \]

\[ \text{airships where the mass of fluid displaced is the same as the total weight of the ship, and where consequently the "virtual mass" may require a considerable magnitude. It may be remarked that for investigations of this nature the results would naturally be plotted showing the variation of the non-dimensional resistance coefficient } R/\rho a^2 \text{ either with } \rho a^2 \text{ for various values of } a \text{ or conversely, and for a complete investigation the full range, zero to infinity, of } \rho a^2 \text{ must be covered.} \]

\[ \text{§ (23) EXPERIMENTAL DETERMINATION OF VIRTUAL MASS.—For longitudinal accelerations such experiments have been successfully conducted.} \]

\[ \text{A body dropped from rest and allowed to fall in a fluid till it reaches its limiting velocity, gives at the commencement of the fall } v = 0 \text{ and } a = 0 \text{ finite so that theoretically } a/\rho a^2 = c \text{ while, when the limiting velocity is reached } a = 0 \text{ and } l \text{ finite so that a photographic study of the change in motion then provides sufficient data to determine the virtual mass.} \]

\[ \text{Numerous and careful experiments have been conducted to test the accuracy of the deduction that for non-accelerated motion of a viscous fluid the state of affairs depends merely on the value of } \rho a^2. \text{ Reynolds, as already indicated, showed beyond doubt that for the flow of a liquid in a tube the passage from steady to sinusoidal eddying motion occurs more or less sharply at a definite value of this number. Strom and Pinnell, following up these experiments, verified that for a similar result held. Since then numerous predictions from model results in aerodynamical and marine investigations to full scale have completely justified the deductions.} \]

\[ \text{On the other hand, it is clear that the circumstances of the problem must be such as will not involve the origination of properties of the medium presumed non-existent.} \]

\[ \text{§ (24) EFFECT OF COMPRESSIBILITY. — In ballistics, for example, we are concerned with the motion of a body at speeds approaching the velocity of sound, so that one might expect that not merely would energy be lost during the} \]

\[ \text{Cooksey and Levy, Advisory Committee for Aeronautics, E. and M., 492.} \]

\[ \text{Trans. R.S., for cist.} \]

\[ \text{Ibid. A., cent. 100-224.} \]
motion in overcoming viscous forces, but also
in the production of waves: that is to say,
we must now regard the medium as being
both viscous and compressive. Now the
velocity of sound in a medium of elasticity
K, density ρ, and viscosity ν, is given generally by

\[ V = f(\rho, \nu, \theta) = \frac{\sqrt{\frac{K}{\rho}}}{\nu}, \]

equating like dimensions we easily find

\[ x = \frac{\theta}{\rho}, \quad y = -\frac{\nu}{\nu}, \quad z = 0, \]

\[ \therefore V = A \sqrt{\frac{\rho}{\nu}}. \]

To find the modified expression for the resistance
in this case we write

\[ R = f(\rho, \nu, \theta, \nu) \]

and following the normal procedure we derive

\[ R = \frac{\rho^2 \nu^2 f(\nu, V)}{\nu^2 f(\nu, V)}, \]

\[ R = \frac{\nu^2 f(\nu, V)}{\nu^2 f(\nu, V)}. \]

where V is the velocity of sound in the medium,
indicating that for a given value of \( \nu \), the
resistance coefficient depends solely on the
ratio of the velocity of the projectile to the
velocity of sound.

§ (29) EFFECT OF ROTATION: PROPELLER: Swirl.—If in addition the body possesses a
spin \( \Omega \) due to rifling, there would be present a
term \( \Omega / \nu \),

\[ R = \frac{\nu^2 f(\nu, V)}{\nu^2 f(\nu, V)}. \]

Two points of importance may be noted. In
the first place for such high speeds as would
cause the elasticity of the medium to play an
important part, the value of \( \nu \) would in
general be so large as already to be well above
the range for so-called scale variation for the
viscous forces; that is to say, further increase
in value of the term \( \nu \) would have no marked
influence on the value of the resistance co-
efficient. In the second case, problems of
practical importance involving the rotation
of moving bodies divide themselves under two
heads; these in which the term \( \Omega / \nu \) is of
principle importance as in the case of the
propeller; and those in which the spin has no
appreciable effect on the resistance as in the
case of bodies symmetrical about the axis of
rotation—shells, bullets, etc. In the latter
case the rotation exists only for purposes of
stability and directivity, and plays no measurable
part in affecting the resistance. Restraining
ourselves to the second part, experiments on bullets conducted prior to and
during the war (1914-18) have succeeded in
providing a more or less complete representa-
tion of the forces on a projectile (shell) for

\[ A \] discussion of the performance of propellers as
a function of the non-dimensional group \( \Omega / \nu \) will
be found under "Propellers."
under the influence of the heated surfaces may
attain some considerable importance in the
transmission of the heat, and as a consequence
the quantity \( \delta \) is introduced, representing the
change in density per unit change in temperature,
or
\[
\delta = \frac{\Delta}{\Theta}.
\]

\[\therefore [\delta] = M_1 L^{-3} T^{-1} A^{-1}.
\]

$\S$ (28) RATE OF COOLING OF BODY IN
QUIESCENT GAS.—As an illustration of the
utility of the method of dimensions in the
discussion of problems of cooling, consider
the rate of loss of heat \( h \) of a body of given
shape, of size \( l \) of one part, in a quiescent
atmosphere of density \( \rho \) and kinematic
viscosity \( \nu \). If \( \kappa \) and \( \sigma \) have the
meanings previously attached to them and \( \Theta \) be the
temperature difference maintained between the
body and the gas at a great distance, at which
the latter is undisturbed by the presence of the
body, it will be justifiable to write
\[
h = f(\kappa, \sigma, \rho, \nu, \Theta),
\]
assuming that in this case the changes in
density with temperature are not sufficient to
affect the question. The modifications intro-
duced if this condition is violated will be
apparent, and adjustment easily made.

Integrating the function \( f \) expanded as in previous
illustrations in the form
\[
\Sigma \frac{1}{\kappa} \frac{1}{\sigma} \frac{1}{\rho} \frac{1}{\nu} \frac{1}{\Theta},
\]
then
\[
[h] = [f] M_1 L^{-3} A^{-1}.
\]
The dimensions of \( h \), the rate of heat loss, are those of
(Heat)/(Time) = M_1 L^0 T^{-2} A^{-1}.

\[
[r] = M_1 L^{-2} A_1, \quad y = y + 1, \quad z = z + 1,
\]
\[
[\Theta] = [\kappa], \quad \nu = \nu + 1, \quad \rho = \rho - 1,
\]
\[
[\Theta] = [\sigma], \quad \kappa = \kappa - 1,
\]
\[
[x] = x + 1, \quad \nu = \nu + 1, \quad \rho = \rho + 1
\]

This provides a typical term in the expansion in the
form
\[
H(\theta) \left( \frac{M^2 R^2}{\pi^2 \kappa} \right) \left( \frac{1}{\Theta} \right)
\]
and consequently since \( \kappa, \nu, \rho \) and the
mean value of each term may be found to be
any value whatever, it is to be concluded that
\[
h = \theta H(\theta) \left( \frac{p^2 R^2}{\pi^2 \kappa} \right) \left( \frac{1}{\Theta} \right).
\]

Whether or not all the quantities which have
been assumed of importance in the deter-
mation of \( h \) morally do enter in a question
to be decided only by experiment, to which
we shall return shortly.

$\S$ (29) NON-DIMENSIONAL VARIABLES.—
For the moment it can be concluded that the
problem of rate of cooling in this instance reduces itself to a consideration of the variation of $h$ along, not of the non-dimensional group $h/\ell k\theta$ with the non-dimensional variants $g\ell^2/\ell^2 c\ell / c$ and $c\ell / k$. If we are dealing with the rate of cooling in gases then practically $c\ell / k$, the ratio of the emissivities for momentum and for heat, is a constant for all gases, and consequently this term may be omitted from the function $f$.

A considerable number of experimental investigations have been conducted on this problem and in all cases it has been found that the rate of heat loss varies directly as the temperature difference $\theta$. In effect this implies that $h/\ell k\theta$ is independent of $\theta$ and that consequently $f(c\ell^2/\ell^2 c\ell / c)$ above is a constant. Hence

$$h = f(c\ell^2/\ell^2 c\ell / c),$$

indicating that the rate of cooling is proportional to the size of the body and to the conductivity. This coefficient $f$ depends on the shape of the cooling body.

If, however, it is legitimate to assume that the expansion of the gas due to heating is negligible as a factor in heat transmission, but that the expanded portions become thereby relatively lighter will tend to stream upwards, and as a consequence the heavier portions downwards, a new term introducing the change in weight of unit volume per unit change in temperature must be considered. Such a factor is of course $g(\ell^2/\ell^2 c\ell / c)$ or $g\ell^2$. Hence generally

$$h = f(c\ell^2/\ell^2 c\ell / c)$$

and following the lines of the previous argument

$$h = f(c\ell^2/\ell^2 c\ell / c).$$

For the reasons adduced in the former case, the final form sufficiently approximate for all practical purposes is

$$h = f(c\ell^2/\ell^2 c\ell / c).$$

provided the problem is restricted to heat transmission in gases. The form of the function $f$ depending as it does on the shape of the body under consideration, will now be completely determined graphically from a single set of experiments for which the non-dimensional group $g\ell^2/\ell^2 c\ell / c$ is allowed to vary over a range, for each point of which the non-dimensional term $h/\ell k\theta$ is measured. The resulting curves obtained, invariably for all systems of units, will then be characteristic of those special boundaries.

§ (20) RATE OF COOLING OF A MOVING BODY IN A GAS.—Problems of great practical importance arise in connection with the rate of heat transmission from bodies in motion in the air, as in the case of radiators and air-conditioned engines. In these problems the rate of heat transmission will actually depend on the translational velocity $V$ in addition to the quantities already enumerated above. The introduction of this extra symbol, as can easily be verified by an application of the dimensional method, gives rise to the “fluid friction” term $V^2/\ell k\theta$ in the functional expression. If under these circumstances it can legitimately be presumed that the term brought in by the rate of change of density would not materially affect the rate of heat transmission, an assumption that will be examined shortly, then, for reasons already set forth,

$$h = f(c\ell^2/\ell^2 c\ell / c).$$

or, since $c\ell / k$ is constant for a gas,

$$h = f(c\ell^2/\ell^2 c\ell / c).$$

§ (21) EXPERIMENTAL DETERMINATION OF UNKNOWN FUNCTION.—In the case of heat loss from long circular wires past which air is streaming with velocity $V$, it has been found that $h$ varies approximately as $V^2$. If for the moment this be accepted as correct, it is possible immediately to determine the form of the function, for the only expression for $f$ such as will make $h = f(V^2)$ is $h = f(V^2/\ell k\theta)$. If the wire, moreover, is of diameter $c$, it is quite legitimate to substitute $a$ for $l$ in this term in order that when the wire is of infinite length there may result a finite heat loss per unit length. It follows, therefore, on the foregoing assumption that

$$h = f(V^2/\ell^2 c\ell / c).$$

since $c\ell / k$ is constant.

The most rational method of representing graphically the experimental results referred to above would be by plotting the non-dimensional term $h/\ell k\theta$ on the non-dimensional basis $V^2/\ell^2 c\ell / c$, from which, if the above law is exact, a straight line would be obtained characteristic of that particular shape of wire.

§ (22) DYNAMICAL SIMILARITY.—It should be remarked that if $V^2/\ell k\theta$ and $g\ell^2/\ell^2 c\ell / c$ are maintained constant from problem to problem, the system of stream lines and state of flow generally will remain geometrically similar, for the velocity $V$ at any point geometrically fixed with respect to the body will be of the form

$$V = f(V^2/\ell^2 c\ell / c),$$

and the argument follows closely that adopted in the case of the motion of viscous fluids, already outlined.

More recent investigations of the rate of cooling of wires in a current of air, by L. V.,

DYNAMICAL SIMILARITY, THE PRINCIPLES OF

have shown the presence of another
possesses that involving \( V^2 \), viz. a term
turned by the square of the linear dimen-
the hot body. King in fact found close
approximation to the results he
for the rate of heat transmission by
the empirical formula:

\[ A = (\theta - \theta_0) [A \sqrt{V} + B + C] \]

A, B, and C are constants for the
and shape of wire—circular in
L. R. Richardson \(^2\) has suggested
in presence of the term \( \theta - \theta_0 \) as
that the velocity near the hot body
by produced by the rising of fluid due
furnace expansion. It follows, therefore,
that the additional term to be expressible in terms of the
magnetic groups already referred to, viz.

\[ \text{More Accurate Determination of Own Function.} \]

Writing therefore

\[ z = k (\theta - \theta_0) (\frac{aV^2 \mu \cdot d\theta}{k}) \]

From dimensional reasoning and
this to the empirical formula found

\[ \sqrt{V} + B + C = k \left( \frac{aV^2 \mu \cdot d\theta}{k} \right) \]

Limited, therefore, the form of the function to

\[ I^2 = \sqrt{\left( \frac{aV^2 \mu \cdot d\theta}{k} \right) + Q + R \cdot \frac{\mu \cdot d\theta}{c}} \cdot \frac{\mu \cdot d\theta}{c} \]

P, Q, and R are new pure numbers
independently by the geometrical conditions
inversely applicable for any gas once.
most of these numbers have been
from King's experimental results.

Dynamo formula is consequently

\[ (\theta - \theta_0) \left[ I^2 = \sqrt{\left( \frac{aV^2 \mu \cdot d\theta}{k} \right) + Q + R \cdot \frac{\mu \cdot d\theta}{c}} \cdot \frac{\mu \cdot d\theta}{c} \right] \]

the relation between the rates of heat
of the remaining quantities \( k, \mu, \cdot \)
were not presumed variable in the

Non-dimensional Groups are the

11. Dimensions of Electric and Magnetic Quantities

§ 35. Electrostatics.—The treatment of electrical and magnetic phenomena from the standpoint of the present article presents some points of interest. Considering in the first place electrostatic quantities, we possess at present no means of expressing electric or magnetic charge directly in terms of any of the fundamental units already introduced. Accordingly the consideration of electrostatic quantities must introduce a new unit directly related to the charge. The simplest method of representation is through the quantity \( K \), the

specific inductive capacity, and the experimentally known law of force between charged bodies. Accordingly we write

\[ \frac{1}{K} \cdot \frac{\text{force}}{r^2} = \text{charge} \]

giving the dimensions of a charge \( [K \cdot \mu]^2 \cdot T^{-1} \)

At once, from the definition of the quantities concerned, it is possible to draw up the following table:

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Symbol</th>
<th>Dimension</th>
</tr>
</thead>
<tbody>
<tr>
<td>Charge</td>
<td>( n )</td>
<td>( K \cdot \mu^2 \cdot T^{-1} )</td>
</tr>
<tr>
<td>Electric intensity</td>
<td>( F )</td>
<td>( K \cdot \mu^2 \cdot T^{-1} )</td>
</tr>
<tr>
<td>Potential difference</td>
<td>( V )</td>
<td>( K \cdot \mu^2 \cdot T^{-1} )</td>
</tr>
<tr>
<td>Current</td>
<td>( i )</td>
<td>( K \cdot \mu^2 \cdot T^{-1} )</td>
</tr>
<tr>
<td>Resistance</td>
<td>( R )</td>
<td>( K^{-1} \cdot L \cdot T )</td>
</tr>
<tr>
<td>Capacity</td>
<td>( C )</td>
<td>( K )</td>
</tr>
<tr>
<td>Specific (independent) capacity</td>
<td>( K )</td>
<td>( K )</td>
</tr>
</tbody>
</table>

In the same manner, commencing with the definition of magnetic permeability \( \mu \) as

\[ \frac{1}{\mu} \cdot \frac{\text{force}}{r^2} = \text{charge} \]

and \( m \) and \( m' \) being the strength of two magnetic poles, we can draw up a parallel list of quantities involved in magnetic phenomena, e.g. strength of magnetic pole has dimensions \( K \cdot \mu^2 \cdot T^{-1} \). It would appear at first sight as if these two lists were quite independent and that two separate units, \( K \) and \( \mu \), for the discussion of electric and magnetic phenomena would require to be introduced, but it is known that magnetic and electric phenomena are closely interwoven, that currents flowing through wires originate magnetic fields in their neighbourhood.

§ 36. Relation between Electrical and Magnetic Units.—We have in fact this connecting link, that if a magnetic pole of strength \( m \) is made to thread a circuit once in which is

---

\( \text{Note: Text copied with minor formatting adjustments for readability.} \)
flowing a current of strength \( i \), the total work done is measured by

\[
\text{work done} = \int i \, dx.
\]

Hence the dimension of the product of magnetic strength and electric current are those of work.

\[
\begin{align*}
\text{L}_1 & = \text{M}^1 \text{I}^1 \text{T}^{-1} \text{E}^{-1}, \\
\text{L}_2 & = \text{M}^1 \text{I}^1 \text{T}^{-1} \text{E}^{-1}.
\end{align*}
\]

The most natural standard velocity to adopt in such circumstances would be the velocity of electromagnetic waves in the particular medium, and accordingly, we have the relation

\[
\mu K = \Lambda / V^2,
\]

where \( \Lambda \) is some constant which accurate experimental investigations have, in fact, shown to be equal to unity. This simple yet fundamental relation between \( \mu \) and \( K \) enables us at once to reduce the two systems of units to one, either by expressing all the electrical quantities in terms of magnetic units or vice versa. We express them here in terms of electromagnetic units as follows:

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Symbol</th>
<th>Dimension</th>
</tr>
</thead>
<tbody>
<tr>
<td>Charge</td>
<td>( e )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 )</td>
</tr>
<tr>
<td>Electric intensity</td>
<td>( E )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{T}^{-2} )</td>
</tr>
<tr>
<td>Potential difference</td>
<td>( V )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{T}^{-2} )</td>
</tr>
<tr>
<td>Current</td>
<td>( i )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{T}^{-1} )</td>
</tr>
<tr>
<td>Resistance</td>
<td>( R )</td>
<td>( \mu \text{I}^1 \text{T}^{-1} )</td>
</tr>
<tr>
<td>Capacity</td>
<td>( C )</td>
<td>( \mu^{-1} \text{I}^1 \text{T}^{2} )</td>
</tr>
<tr>
<td>Specific independent capacity</td>
<td>( K )</td>
<td>( \mu^{-1} \text{I}^1 \text{T}^{2} )</td>
</tr>
<tr>
<td>Strength of magnetic field</td>
<td>( H )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{T}^{-1} )</td>
</tr>
<tr>
<td>Magnetic force</td>
<td>( F )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{L}^{-1} \text{T}^{-1} )</td>
</tr>
<tr>
<td>Magnetic induction</td>
<td>( B )</td>
<td>( \mu^{-1} \text{M}^1 \text{I}^1 \text{L}^{-1} \text{T}^{-1} )</td>
</tr>
<tr>
<td>Magnetic permeability</td>
<td>( \mu )</td>
<td>( \mu )</td>
</tr>
<tr>
<td>Coefficient of induction</td>
<td>( \lambda )</td>
<td>( \mu \text{L} )</td>
</tr>
</tbody>
</table>

By means of these dimensional relations it is possible once more to group together whole classes of investigations as dependent on the variation of certain non-dimensional groups, thus indicating a rational method of plotting the results obtained.

§ (37) APLICATION OF THE PRINCIPLES OF SIMILITUDE TO MODELS

§ (38) MODEL EXPERIMENTS AND THEIR FULL-SCALE EQUIVALENTS.—The principles developed in the foregoing paragraphs, serving as they do to group together processes occurring in geometrically similar systems, provide the most natural method of approach to the problem of the relations of models to their full-scale counterparts. The lines of development in the case of the use of models for the determination of the wind forces on aircraft have already been discussed. Two further aspects of the general question will be here treated. What, in the first place, must a model fulfill as regards working conditions in order that its motions and working may be directly comparable with those of the full-sized machine? That is to say, what are the relations between weights, external forces, speeds, etc., that two systems initially geometrically similar may continue during their motion to remain geometrically similar, that the relative positions of the parts of one system after a time \( t \) may always be similarly situated to the relative positions of the corresponding parts at time \( t' \), where \( t \) and \( t' \) bear a constant ratio to each other. It is clear that if these conditions can be determined and a model produced to operate satisfactorily while working under them, then the full-scale machine will also operate satisfactorily. The second aspect, dealing with the strength of construction of the model and of the full-scale, will be treated shortly.
§ (30) **Condition for continued Similarity in Working of Model and Full-Scale.**—Corresponding to each part of the system there will be a scheme of equations between the moving forces and accelerations produced, of the form \( w_0(d^2x/dt^2) = X \) for the model, and for the full-sized machine \( w'(d^2x'/dt^2) = X' \), where \( w \) and \( w' \) are the masses of corresponding parts, occupying corresponding positions \( x \) and \( x' \) at corresponding times \( t \) and \( t' \). \( X \) and \( X' \) are the corresponding moving forces. For continued geometrical similarity at time \( t \) and \( t' \) connected by \( t = t'/F \), where \( F \) is some constant, there must be \( x = x'/F \), \( M = M'F^2 \), and \( X = X'F^2 \) where \( t, M, \) and \( F \) are constants determining the scale of the one with reference to the other. Hence, inserting these in the first equation,

\[
\frac{M}{t^3} \frac{d^2x}{dt^2} = \frac{X}{t'F^2}
\]

and the motions will therefore remain identical if \( M/t^3F^2 = 1 \), the same equation then applying both to model and full-scale. Hence the moving forces of model and full-scale must be

\[
F = \frac{M}{t'^3}
\]

In the same way, had the corresponding times been eliminated by comparing the systems at corresponding speeds we would have found that for similarity the moving forces must be proportional to \( MVF \).

The following conclusions may accordingly be drawn for a comparison of the working of a model with that of the full-sized machine:

- Since the weights of the parts, regarded as external forces, are proportional to their masses, \( V = \text{const} \), and the velocity of working must be proportional to the square root of the linear dimensions; external moving forces must have a constant ratio to the weight and must therefore increase as the cube of the linear dimensions, if model and machine are made of the same material.

**IV. SIMILARITY OF STRUCTURES**

§ (40) **Structural Strength.**—Turning to the question of the relation between the structural strengths of models and full-scale constructions, it is proposed to show that the theoretical basis of model strength tests on structures may be developed in a rigorous yet simple form by an application of the method of Dimensions.

When a homogeneous prismatic strut of length \( L \) and flexural rigidity \( EI \), simply supported at the ends, is subjected to axial end thrust \( F \) up to a load given by

\[
F = \frac{\pi^2EI}{L^3}
\]

the undeteracted position in one of stable equilibrium provided the ultimate stress is not exceeded. Beyond this so-called Euler's Critical Load, the straight position is one of unstable equilibrium. If the strut be deflected, as long as the load is maintained the axis will continually undergo change in shape until it ultimately takes up a form of elastic. During this process the yield point of the material may be exceeded and the material may rupture. The strut may thus be supposed to fail for two possible reasons, on the one hand because its shape has been permanently changed from the straight normal position owing to the instability of that position, and on the other hand because the actual material has failed to withstand the stresses originated. This conception is of course not limited to such a simple structure as a strut, for it may be seen that in general a framework of any kind may fail for either of these two reasons. It is proposed to investigate what information may be furnished regarding these two types of failure, rupture and instability, for a structure in general, by an application of the dimensional theory.

Consider the case of a structure of the type of an aeroplane framework for definiteness, although the argument is quite general, where it is supposed that the assumptions made in the ordinary beam theory apply to every part. Let the length of one part, say a bay, be given by \( l \), the area of a particular section by \( A \), moment of inertia \( I \), and the elasticity and density of the material of which it is composed \( E \) and \( \rho \) respectively. Given these quantities for this one portion, it will be assumed that the shape and geometry of the structure involve an exact specification of how to derive the corresponding quantities for the remaining portions. Let the external load be \( F \), applied in some given manner specified geometrically, and suppose this is sufficient to produce a stress just greater than the yield stress \( f \) in the material of the weakest member. \( F \) can only depend apart from the geometry and manner of application upon the quantities enumerated above, defining the properties of the material. These are as follows:

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Symbol</th>
<th>Dimensions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Young's modulus</td>
<td>( E )</td>
<td>( M/1T^2 )</td>
</tr>
<tr>
<td>Area</td>
<td>( A )</td>
<td>( L^2 )</td>
</tr>
<tr>
<td>Moment of inertia</td>
<td>( I )</td>
<td>( L^2 )</td>
</tr>
<tr>
<td>Length</td>
<td>( L )</td>
<td>( L^2 )</td>
</tr>
<tr>
<td>Density</td>
<td>( \rho )</td>
<td>( M/1 )</td>
</tr>
<tr>
<td>Yielding stress</td>
<td>( f )</td>
<td>( M/1T^2 )</td>
</tr>
<tr>
<td>Gravity</td>
<td>( g )</td>
<td>( L/1T^2 )</td>
</tr>
<tr>
<td>Load</td>
<td>( F )</td>
<td>( M/1T^2 )</td>
</tr>
</tbody>
</table>

Since \( F \), the load which will cause collapse by rupture of the material, must involve these quantities grouped together in such a
number us to make the dimensions of the product identical with those of \( F \), we may write
\[
F = \phi(E, A, I, l, \rho, f, \phi).
\]
Applying the method already used frequently in this discussion, we easily find
\[
F = \frac{E}{E} \left[ \left( \frac{f}{E} \right) A W I \right],
\]
where \( \phi \) for the moment is an arbitrary function.
Writing
\[
\phi^* = \frac{F}{E}
\]
so that this quantity may be considered as a non-dimensional critical loading coefficient, it follows finally that
\[
\phi^* = \phi \left( \frac{f}{E} \right) W A I.
\]
§ (41) Non-dimensional Critical Loading Coefficient. — It is clear from the definition of \( \phi \) that for a given structure where \( I, E \), and \( f \) are known \( \phi \) is uniquely determined when \( F \), the breaking load, is found, so that the discussion of collapse by rupture may equally well be central round \( \phi \). Let it be clearly understood that the exact form of the function \( \phi \) above depends only on the geometry of the structure, including the manner of loading and the law of distribution of load.

Out of the general class of framework considered in this discussion so far, let there be selected a series of which all members are identical with respect to external shape, differing only in scale. This implies that, the area of cross-section of any selected part, is proportional to \( P \) and to \( E \). For this series, therefore, \( A/E \) and \( H/E \) are constants depending only on the geometry, and accordingly the expression for \( \phi \) now takes the simplified form
\[
\phi^* = \phi \left( \frac{f}{E} \right) W A I.
\]
It is not difficult to give an interpretation to the two non-dimensional quantities \( f/E \) and \( W/A \). The former, being the ratio of the yielding stress to Young's modulus, may be taken as the strain at the yield point, on the assumption that Hooke's Law applies rigorously over the whole range. In the same way \( W/A \) is the ratio of the weight of a particular member, say the weakest, to the maximum tensile or compressive force it can withstand at the point of yield. It is equally clear, however, that the so-called geometrical restrictions determining the distribution of the constants of the material in a composite structure are not absolutely vital to the above discussion, so that violations of the laws determining the selection of the material from member to member would not necessarily vitiate the conclusions arrived at here. For example, one would not be rigorously entitled to vary \( I, A, \) and \( E \) in equal parts, since such a change would clearly upset the geometrical similarity of shape and the distribution of force, with the possible result that the previously weakest member might not remain such. No such trouble, however, could arise if the selection of the materials was made without changing these factors, but allowing a variation in \( f \), the yielding stress, so long as the previously weakest member always remains so in the series. This is equivalent to an increased latitude in the scope of selection of material.

Generally in experimenting with a model of this nature it is convenient, of course, to have corresponding parts in the model and the full-scale structure composed of identical materials. If, for example, the frame of a similar was under discussion, when in the model would be composed of the same metal as those in the original; corresponding struts, spars, ribs, etc., of the same metal.

Since the quantities \( f, E, I, \rho \), etc., in the expressions for \( \phi^* \) all refer ultimately to the same part of the model, to ensure geometrical similarity in the widest sense it follows that the assumption that \( f/E \) is a constant is one which it is obvious experimentally. Under these circumstances also \( W/A \), as can easily be verified, becomes proportional to the linear dimension \( E \). The breaking load coefficient \( \phi^* \), therefore, when the weight of the structure contributes to rupture, is purely a function of \( E \),
\[
\phi^* = \phi_0(E),
\]
and the form of the function is determined only by the shape of the various parts, the geometry of the loading and the so-called geometry of the material.

§ (43) Limiting Size of a Heavy Structure. — This expression for \( \phi^* \) may likewise be supposed solved for \( E \) in terms of \( \phi^* \). But every external load coefficient this equation then determines the size of the structure corresponding to failure. When there is no external load and failure is due to weight alone, \( \phi_0(E) = \Omega \), an equation determining the smallest size of a structure that will collapse under its own weight.

When the material is not sufficiently heavy to involve the weight of the structure appreciably as a factor in causing collapse, the term
DYNAMICAL SIMILARITY, THE PRINCIPLES OF

W/\alpha may be omitted in the general equation and the expression for \phi^2 takes the relatively simple form

$$\phi^2 = \phi_0 \left( \frac{f}{E} \right).$$

§ (44) NON-DIMENSIONAL BASIS, AND "CHARACTERISTIC CURVE."—Let us imagine that the weakest member is replaced by another of the same geometrical shape and size but with a different value of \(f/E\), though not so different as to prevent its remaining the weakest member; then a test on each one of these models will give a particular value of \(\phi^2\), breaking load constant, and these when plotted against \(f/E\) will give a "characteristic curve" for the structure of the given geometry. For geometrically similar structures of which the corresponding parts are made of the same material, so that \(f/E\) is constant, the breaking load coefficient becomes an absolute constant for the series depending for its value purely on the shape. It follows that a single test on destruction on a model will suffice for these conditions to determine the breaking load coefficient \(\phi^2\), and therefore the breaking load \(P\) for any other member of the series of geometrically similar structures.

§ (45) FAILURE DUE TO INSTABILITY.—It is assumed in this section that the failure is not necessarily accompanied by collapse or rupture in the material, but is due merely to permanent deformation of the configuration of the structure. It follows that, in the expression for the critical load, the yield stress does not enter although all the other terms \(A, l, E, l, \rho, g\) may do so. Using \(\phi^2\) as a critical load coefficient defined by \(fP/E\alpha = \phi^2\), then

$$\phi^2 = \phi_1 \left( \frac{A \cdot W \cdot I}{E \cdot \alpha \cdot \beta^2} \right),$$

obtained by the same method as in the previous section.

On the understanding that the structures in the series are all geometrically similar as regards external shape without reference to material composing them, then \(A^2\) and \(I^2\) are constants for the series, and

$$\phi^2 = \phi_2 \left( \frac{W}{E \alpha} \right),$$

where \(W/\alpha\) is the ratio of the weight of a member to the tensile or compressive force required to produce unit strain at some particular section of that member.

If corresponding members of the series are made of the same material, then \(W/\alpha\) is easily seen to be proportional to \(l\), from structure to structure, and as before the critical loading coefficient

$$\phi^2 = \phi_3 (l)$$

depends on the size only.

§ (46) CRITICAL LOADING COEFFICIENT A CONSTANT FOR COLLAPSING DUE TO INSTABILITY.

When the weight of the structure is negligible as far as its effect in contributing to failure is concerned, the whole instability arising from the external loading, then \(\phi^2\) is a constant for a series of structures of identical form irrespective of the material of which it is composed, and a test to destruction on one model suffices for the series.

It has been found that the critical loading for a uniform prismatic strut of negligible weight under end thrusts and simply supported at the ends is given by

$$P = \frac{\pi^2 E I}{\mu}$$

so that \(\phi\) for this structure is \(\pi\). For a strut under the same conditions, but with clamped ends, \(\phi = 2\).

In certain cases of simple shapes of structures, it is obvious that the function \(\phi\) may be derived by calculation, as for example in the above two cases, but for more complicated problems where the calculation is too arduous a number of points on the characteristic curve may be derived by a series of tests to destruction on models.

In the special cases where \(\phi\) is a constant for the series a single test on one model is clearly sufficient. This, as has been shown, applies with equal force when the collapse is due either to instability or to failure of the material.

The basis of the experimental method thus having being made secure, no scale effect difficulty of the type normally arising in any aerodynamic work being present, it should now be possible to proceed to a direct accurate test of failure and its causes under various circumstances.

§ (47) WHIRLホール OF SHAPES.—While the foregoing analysis applies to structures under forces of the static type, a parallel argument can be applied where fluctuating stresses are introduced, or where parts of the structure are in motion. In illustration consider the problem of whirling of a rotating shaft of given outline and section. As before, suppose the geometrical shape longitudinally and cross-sectionally to be given, length \(l\), mass per unit length \(m\), and flexural rigidity of a particular section \(EI\); then if \(g\) be the speed of rotation, the deflection \(d\) at the centre, say, will be a function of \(l\), \(m\), \(E\), \(I\), and \(g\), i.e.

$$d = f(l, m, E, I, g).$$

Hence

$$\frac{d}{l} = F \left( \frac{mg^2}{EI}, \frac{g}{l} \right)$$

on equating the dimensions of the typical group. For a shaft of given geometrical outline \(EI\) is a constant dependent on the geometry, hence in varying the size of geometrically similar shafts the ratio of the deflection at the centre to the total length will depend only on the quantity \(mg^2/EI\).
§ (48) Non-dimensional Variables.—If a whirling speed exists, then, for some value of \( q \), the ratio \( \frac{a}{P} \) will theoretically become infinite, or at least indeterminate, and this can only occur for some value of the variable \( \alpha \), for which the variable \( \frac{a}{P} \) may be. Hence we find that the real variable in whirling shaft problems is the size and material of the shaft are varied, but maintaining the geometrical shape constant, is \( \frac{a}{P} \). In actual fact the whirling speed of a straight shaft is known to be

\[ q = \frac{P}{m} \sqrt{\frac{a}{E_i}} \]

i.e.

\[ \alpha = \frac{a}{P} = q^2 \]

and for a homogeneous circular stepped shaft made up of three portions, the two end pieces of length \( l/4 \) and diameter \( d/4 \), and the central portion of length \( l/2 \) and diameter \( d \),

\[ \alpha = \frac{a}{P} \]

is, being taken for the central portion.¹

From the foregoing analysis, moreover, it is apparent that shafts of identical geometry but differing in size and material will maintain their identity in geometry under rotation provided they be compared at corresponding speeds \( q_1 \) and \( q_2 \) given by

\[ q_1^2 \sqrt{\frac{m_1}{E_1}} = q_2^2 \sqrt{\frac{m_2}{E_2}} \]

§ (49) Expansion in Terms of the Class Variables.—It has become apparent in the application of the method of the present article to various branches of physics and engineering that in all cases the investigation has centered itself round the behaviour of some expression represented as a function of a certain non-dimensional group of terms. This quantity, connecting together as it were a whole class of problems possessing certain geometrical and dynamical similarities, may be termed the class variable. Many problems in mathematical physics expressible in terms of differential equations would appear then to demand a solution as a function of the class variable, and accordingly an expansion of the solution of the differential equation is sought for as a power series in the class variable. This method has been applied with considerable success to the problem of the striping of struts, the whirling of shafts of variable flexural rigidity, and to the motion of a viscous fluid.² In effect this is simply an analytical method of representing the "characteristic curves" on non-dimensional axes obtained so frequently in the foregoing discussion.

Dynamical Similarity

Experimental verification of Rayleigh’s conditions for the motion of fluids in contact with solid boundaries. See "Friction," § (15).

Rayleigh’s method of determining the essential conditions which must be fulfilled. See ibid. § (16).

Dynamical Similarities, Application of Dynamical Similarity to. See "Dynamical Similarity, The Principles of," § (7).

DYNAOMETERS

§ (1) Fundamental Principles.—The work done by a prime mover or other agent when transmitted by a rotating shaft may be expressed by \( P_2 \) and when by a moving chain, rope, or similar agent, by \( P_c \), where \( P \) is the force acting. \( \phi \) the torque arm, \( \phi \) the angular displacement, and \( d \) the linear displacement.

A dynamometer is an instrument which is used for the measurement of the force \( P \) or the torque \( P_c \); the values of the quantities \( \phi \) and \( d \) are usually determined independently.

The work done by the prime mover may either be absorbed by the dynamometer or transmitted to a machine in which it is employed usefully after having been measured.

It is necessary that the instrument adopted should perform its function with accuracy. The whole of the energy developed by the prime mover should be included in the measurement made without neglecting that absorbed by shaft bearings in the dynamometer itself or by gearing or bearings which may be interposed between the prime mover and the dynamometer.

The bearing should be capable of fine adjustment under varying conditions, and this adjustment should preferably be over a considerable range of power in order that the prime mover may be tested from its minimum to its maximum power capacity without the necessity for frequently stopping down.

The construction of a dynamometer should be such that it imposes no force on the prime mover other than that for which it was designed. For example, a dynamometer suitable for testing a petrol motor should exert a pure torque, otherwise the motor bearings will be called upon to take loads, and the shaft to resist bending and shear stresses, additional to those for which they were intended.

It is desirable, in the type of dynamometer in which the power is absorbed, that the inertia of the rotating parts should be small in order that a stoppage may readily be effected if failure of the prime mover should occur, as the energy stored in a heavy rotor

DYNAMOMETERS

revolving at a high speed may be sufficient to cause very serious damage.

In order that accurate measurements may be made, it is essential that the dynamometer should apply the load extremely steadily; otherwise violent oscillations will be set up rendering the employment of heavy dash pots unnecessary, which is undesirable.

The variation of load with speed for the same setting of the apparatus should be such that "slipping" of the load is eliminated.

(1.) Absorption Dynamometers.—In these the energy generated is converted either into heat by the intermediary of solid or fluid friction, or into electrical energy by means of a generator.

The apparatus in most common use is the fluid friction brake, this being simple in construction, easy to regulate over a wide range, and extremely steady in action.

The solid friction brake for large powers requires considerable experience in manipulation in order to avoid mutuality due to violent smacking of the load. In its simplest form for small powers, that of the rope brake, it is a very efficient and accurate brake and runs very steadily if proper precautions are taken.

(2.) Transmission Dynamometers, for the measurement of power transmitted by a shaft, exist in three fairly common forms, viz.: (1) Torsionometers, in which the angle of twist of a length of the shaft due to torsional stress is measured either optically or by mechanical means.

(2) Torqueometers, in which the torque load is transmitted by springs, or by hydraulic plungers, the extensions of the former and the fluid pressure set up by the latter being indicated or recorded.

(3) Instruments for measuring the power transmitted by means of a belt on the shaft of the prime mover.

The last very considerably in form but the object achieved is the same in each case, viz., the measurement of the difference in tension of the belt on either side of the driven pulley.

Another important form of the transmission dynamometer is the traction motor for the measurement of the tractive effort of self-propelled vehicles. Dynamometers have been designed for measuring and recording the tractive effort of locomotives, motor cars, and traction engines and the tractive resistance of railway carriages, wagons, wheels, and ploughs.

§ (2) Absorption Dynamometers. (1) The Prony Brake.—In its original form this brake consisted of two stout beams of wood clamped upon the shaft or on a pulley fixed thereto. The beams were suitably bored in order to grip a large proportion of the circumference of the shaft, and the nuts on the clamping bolts served as a means of adjusting the frictional resistance between the shaft and the brake. A horizontal arm, usually an extension of the upper beam, supported a load pan on which the weights were hung, a fine adjustment being provided by a jockey weight, the position of which could be adjusted along the beam. The movement of the end of the arm was confined within small limits by rigid stops, one above and one below the arm. Fig. 1 shows diagrammatically the arrangement.

Very liberal lubrication of the frictional surfaces was necessary to ensure smooth running, but at best considerable vibration of the arm took place due to the variation in frictional resistance between the brake and the shaft, the end of the arm oscillating violently between the stops and rendering a good balance difficult to obtain.

The torque T exerted by the shaft when the brake is balanced is represented by 2p where P is the frictional resistance between the brake surfaces, and R the radius of the surfaces; it is measured by the algebraic sum of the moments of the load, jockey weight, and the brake beams about the centre of the shaft.

In calculating the horse-power developed the factor 2 is required and is obtained by means of a tachometer or by revolution counter and stop watch.

The rate at which work is absorbed is expressed by

\[ \text{Horse-power} = \frac{2 \cdot \pi \cdot N}{330} \]

where N is the speed in revolutions per second, and T the torque as measured by the brake in pound feet units.

(6.) Modifications of the Prony Brake.—Several improvements and modifications have been made on the original brake as first used by Prony. They consist chiefly in arranging that the grip of the brake blocks shall automatically alter with the value of the coefficient of friction, thus maintaining the total frictional force and therefore the value of T more or less constant.

The Appold brake is shown in Fig. 2 and is an example of one of many compensating brakes. The wooden blocks forming the brake are connected together by a steel band provided with a hand-adjusting screw at A, the
ends of the steel band being connected to the compensating lever at B and C as shown. The end of the lever D is pivoted to the engine frame. The load is supported, as shown, from a hook attached to the steel band, a pointer being provided to indicate when the hook is level with the centre of the shaft.

In the normal position the hook is opposite the pointer and the lever BD is vertical. When the load is lifted, the lever moving about D as centre rotates with the steel band and virtually increases its length, thus slackening the band and partly relieving the load.

If the load falls, due to the coefficient of friction decreasing, the compensating lever shifts round in the opposite direction, tightens the band, and thus increases the grip and lifts the load.

In practice it is found that nearly as much adjustment of the load is required as without the compensating device, but the chief objection to the brake is that when a heavy torque is being measured the lever rests on the frame with sufficient force to cause an appreciable error in the result obtained if the ordinary method of calculation is adopted.

A better form of compensating brake, but one perhaps not as well known, is that designed by Mr. Balk and originally used by Messrs. Ramsden Sims and Jeffries. It is shown diagrammatically in Fig. 3.

The compensating lever is here outside the disc of the brake wheel, and is connected at B and C to the ends of the strap and the band pan is long from the point D. Suitable stops are provided for the lever. The weight of the brake adjustment load must be taken into consideration in determining the torque; it must be considered as acting as a moment equal to its horizontal distance from the centre of the shaft, and its moment must be deducted from that of the load P.

Solid friction brakes may be used to absorb greater powers if the wheel is water-cooled. The major portion of the energy which is converted into heat is thus quickly dissipated, and one of the chief sources of trouble, namely overheating, is then removed. After a preliminary period of running with water-cooling the brake blocks assume a much constant frictional resistance, rendering the brake much steadier to run.

Water cooling of the wheel is very simply effected by making the rim of the brake wheel of trough section, thus enabling it to hold water when revolving by virtue of the centrifugal forces called into action. Water is supplied by a pipe dipping into the trough at the bottom of the wheel.

The flow is adjusted until a reasonable steady temperature is attained.

(bii) Rope Brakes.—For small powers the rope brakes introduced by the late Lord Kelvin and Professor James Thomson are very successful. The former is illustrated in Fig. 4 and the latter in Fig. 5.

Lord Kelvin's brake consists of a loop of rope wrapped round the fly-wheel of the prime mover, one end of the loop supporting a weight W, the other being held vertically by a spring balance. Wooden blocks are screwed to the ropes in order to keep them properly spaced to prevent the ropes from rubbing together where they leave the wheel tangentially. The wooden blocks are not needed in brake blocks.
If the wheel turns in the direction of the arrow the torque is represented by \((W - w)R\), where \(w\) is the force indicated by the spring balance and \(R\) the radius from the centre of the wheel to the centre of the rope.

When the value of the frictional force changes, the load rises or falls against the action of the spring balance, the brake thus adjusting itself to the new condition.

In using the brake it is advisable to have the ropes and wheel rim either perfectly free from grease, by using new rope and cleaning the wheel rim with petrol, or else thoroughly greased.

If the lubricant is scanty or in patches the weight will hunt, rising and falling regularly, rendering it difficult to obtain a reading of the spring balance with any degree of accuracy.

The brake of Fig. 5 consists of fast and loose pulleys mounted side by side on the driving shaft. It is arranged that a rope draped over the loose pulley hangs down over the fast pulley on one side and over the pulley to which it is fixed on the other.

The frictional resistance between the fast pulley and the rope causes the loose pulley to rotate through a small angle in the direction of rotation of the shaft, and in doing so it lifts a weight suspended by the rope hanging over it. At the same time the rope over the fast pulley, which also supports a weight, is, by the rotation of the loose pulley, slightly unwound from the running pulley, thus reducing its arc of contact, and, therefore, its braking effect. The resistance is thus automatically adjusted.

It should be noted that solid friction brakes, in consequence of the frictional resistance being practically constant over a wide range of speed, cannot be successfully employed for the measurement of power generated by a prime mover, such as a petrol motor in which the torque also remains constant over the same range of speed.

In such a case it is extremely difficult to maintain the speed of the prime mover at even an approximately constant value, and the brake needs continuous attention if steady values of the power are to be obtained.

(iv.) The Krouse Water Brake. The Krouse Water Brake is of the fluid friction type and is very extensively used both commercially and in the laboratory. It consists of a wheel or rotor attached to a driven shaft revolving inside a casing through which water is circulated. The casing is mounted on bearings which enable the shaft at either end but are free from it, and it is free to rotate through a small angle in either direction in bearings offering very little frictional resistance. On both sides of the brake wheel are formed semi-elliptic annular channels divided into pockets by narrow oblique partitions or vanes which are approximately semicircular discs inclined at an angle of 45° to the axis. The vanes on one side of the rotor are inclined at right angles to those on the opposite side, but are also at 45° to the axis. The faces on the inside of the brake casing are formed in the same manner as those of the rotor, the vanes being in the same planes as those on the adjacent rotor face completing the formation of the circular disc inclined at 45°. The number of pockets in the rotor and stator differ by one on each side. The pockets between the rotor and casing thus form complete annular channels of elliptical cross section divided into sections by the vanes. There is only a very small clearance between the faces of the rotor and the casing.

The formation of the channels and vanes is shown in detail in the developed section of rotor and casing in Fig. 6, the section being made by a cylinder passing through the water holes shown in the principal section.

It will be seen that the vanes are inclined at an angle of 45° to the direction of motion, and that those on opposite sides of the centre line are at right angles to each other.

The difference in pitch of the vanes which may be observed is due to the difference in the number of vanes in the rotor and casing respectively.

If, in the view shown, the rotor be moved until one of its vanes comes into line with one of the vanes of the casing, then the line thus
formed is a motion across a diameter of an approximately circular disc, one half of which is formed by the rotor and the other half by the casing. The central disc viewed along the direction of motion has the elliptical appearance shown in the principal sectional view.

When the shaft is rotated, centrifugal action sets up verticals in the pockets in a plane at 45° to the axis, and the slide and case are thus urged in opposite directions also at an angle of 46°.

The components of the forces produced are balanced in the direction parallel to the shaft due to the arrangement of the vanes on opposite sides of the central line, but tangentially they react on the casing. The moment required, therefore, to prevent rotation of the case is equal in the torque on the shaft. The water which is supplied continuously to the brake, when running, passes from pocket to pocket, at the same time rotating at a high rate of speed, finally emerging at a temperature which can be regulated by the supply valve.

The brake is regulated by means of thin sliver gates or plates, inserted between the blades in the rotor and casing. The resistance offered by the brake for a particular setting of the plates varies approximately as the square of the speed, so that the brake is well suited for testing under conditions of constant torque.

The stator case is provided with bearings and packing glands where the shaft passes through it, but the friction of these reacts on the casing and is measured. The case is also provided with a torque arm supported by a spring balance, which in turn is suspended from a hock which can be adjusted in a vertical direction in order that the torque arm shall remain horizontal. The load is hung at the end of the torque arm directly under the spring balance, and the effective torque load is obtained by taking the difference of the load and the spring balance reading.

The effect of the sliver gates is to reduce the effective surface, thus increasing the range of service. The capacity of a dynamometer absorbing 800 horse-power at 800 revolutions a minute can be adjusted to absorb 40 horse-power at 200 revolutions per minute.

(C) Electrical Brakes. The National Physical Laboratory Dynamometer.—In this brake the power developed is absorbed electrically but measured mechanically. The electrical measurement of the power depends in some measure on the accuracy of the instruments employed and on the temperature of the field magnet and armature windings of the generator.

The prime mover under test is coupled directly to the shaft of a generator, the outer frame of which is mounted on bearings offering small frictional resistance, and the torque on this frame is measured. The power generated is carried by very flexible cables to resistance mats by which it is dissipated as heat.

Fig. 7 shows the method of supporting the field magnet frame. The latter is provided with hard steel rings A at either end, these rings being ground truly concentric with the axis of the shaft and securely fixed to the frame.

The rings rest on the sectors B, B, which are also of hard steel ground truly cylindrical on the curved surface with the knife edges at centre. The sectors support the whole weight of the generator, which being thus mounted can oscillate through a small arc with extremely little resistance to motion.

Ball bearings mounted on vertical posts are provided at each end of the generator frame, bearing against the sides of the steel rings to limit the end motion and to take the thrust so that the frame may not be moved too far in a longitudinal direction.

The frame is provided with torque arms, one on each side, so that the torque can be measured when the brake is running in either direction.

The torque arms are balanced and one is provided in the usual manner with means to limit the angle of oscillation.

The load is hung from a knife edge on some of the arms, a fine adjustment being obtained by means of a spring which partly relieves the load. It is arranged that extensions of the spring are magnified and indicated on a moving sheet of paper so that the variation in torque of the prime mover under test are recorded. The paper movement is effected by a clock mechanism, and indications of speed are also recorded electrically.

The arrangement of the recording instrument is clearly shown in the figure.

As in the case of the Frisoe water brakcs, the bearing friction, and incidentally the brush friction, is measured at the torque arm, so that the method affords an accurate means of measuring power. It has the disadvantages of having a small range of power and speed, and a heavy rotor, but these are
somewhat compensated for by the fact that the generator can be used as a motor either for starting an internal combustion engine or for supplying power to a machine whose torque resistance is required to be measured.

It is estimated that, under steady conditions of running, determinations of torque can be made on this dynamometer to an accuracy of 0.1 per cent.

(vi.) Eddy-current Brakes (Fig. 8).—A very successful form of eddy-current brake has been developed by Dr. D. K. Morris and G. A. Lister, and is described fully in a paper to the Birmingham Local Section of the Institution of Electrical Engineers, 1905.

The brake was designed to absorb 5 horse-power at 1000 revolutions per minute, and made for use in the Electrical Laboratory of the University of Birmingham.

The apparatus is made for attachment to the shaft of the prime mover in place of the ordinary pulley, and consists of two elements, one in the form of copper discs fixed to and concentric with the shaft, and the other a circular frame also concentric with the shaft and carrying magnetizing coils at regular intervals round its periphery.

The magnet frame, or slator, is centred by a revolving bush securely keyed to the shaft and is provided with a torque arm, jockey weight, and stops, in the usual manner.

Two copper discs are provided on the rotor, and are fixed to the revolving bush one on either side of the magnet coils, the axes of which are parallel to the shaft axis, and by this arrangement both electrical symmetry and mechanical balance are assured and the brake is rendered static.

The shaft is partly relieved of the weight of the frame by a link suspension attached to an overhead spring balance, and this method of suspension enables the frame to be supported without producing a twisting moment about the shaft centre.

The overhung load on the shaft can be varied as desired by adjusting the tension of the support.

The air gap between the copper discs and the field magnet poles is fixed, and the rigidity of the construction enables it to be made small.

External yoke rings are provided and are supported by brackets from the magnet frame, the brackets being clamped in such a manner that the external gaps between the yoke rings and the copper discs can be adjusted.

The limit of the capacity of the brake is determined by the temperature of the magnet coils.

(vii.) Fan Brakes. The Centrifugal Fan (Fig. 9).—The Centrifugal Fan Brake usually consists of two square or rectangular plates held by radial arms in such a manner that they are presented normally to the direction of motion. The brake is more frequently used as a ready means of applying a load to a shaft.
rotating at a high speed than as a means of measuring torque. It is necessary that it should be calibrated by means of an accurate dynamometer, but the calibration is affected by variations in temperature, pressure of the surrounding atmosphere, cross-currents of air, and the proximity of supports, adjacent walls and floor, and of the prime mover under test.

The load is adjusted either by moving the plates along the radial arms or by fitting plates of a different size, these methods of adjustment having the great disadvantage of necessitating the dismounting of the prime mover under test.

Attempts to render the blades adjustable during rotation have met with little success, owing chiefly to the difficulty of designing the adjusting mechanism to operate against the centrifugal forces acting on the blades.

The torque due to the blades alone, for ordinary speeds and sizes, varies as the square of the speed, the cube of the radius of the blades, the area of the blades, the density of the fluid in which the fan is working, and on a factor depending on the environment.

The fan brake is cheap to manufacture and is usually easy to fit to the shaft of the prime mover. For these reasons it is frequently used commercially as a brake for "running in" and "endurance" tests where the power absorbed is not required to be known with accuracy. It may be used for comparative tests provided the atmospheric conditions and environment remain constant throughout the tests, but neglect of these factors may affect an error of 10 to 20 per cent in the measured torque.

(vii.) The "Escargot" Fan Brake for Testing Aeronautical Engines.—In order to reproduce as far as possible the cooling effect produced on an aeronautical engine under flying conditions, it is essential that the engine under test shall work in a current of air projected on it at a speed comparable with the flying speed.

The cooling is effected in the escargot arrangement by a fan brake driven by the engine under test and mounted in a chamber resembling that of an ordinary fan casing.

The intake of the air is in the side of the casing opposite the fan centre.

Rotary or radial engines are usually mounted inside the escargot, Fig. 10, being then in the direct path of the incoming current of air.

Vee or vertical engines are fixed on a bed outside the escargot, and the air from the discharge orifice is directed on to the engine either from above or from the front.

In the latter arrangement the fan is driven through an intermediate shaft and universal couplings.

For "running in" and "endurance" tests the brake may be calibrated by means of an electric motor, but is open to the objections which have already been summarised under the heading of the "Fan Brake." For tests of greater accuracy it is usual to mount the engine on a floating torque-balance gear by which the reactive torque on the engine may be measured.

When the engine is so mounted it is essential if accurate results are to be obtained, that the axis of the driving frame shall coincide with the fan axis, otherwise the moment measured will differ considerably from the true torque according to the position of the fan in the escargot.

§ (3) Transmission Dynamometers, Tor-...
The mirror is mounted on trunnions working in bearings fixed to the flange, the axis of the trunnions being radial. The mirror is provided with a short radius arm which is connected to an adjustable block on the sleeve by a thin phosphor-bronze link. The tangential movement of the sleeve block is governed by a micrometer screw. In order that the relation between the movement at the radius of the mirror from the centre of the shaft and the spot of light on the scale may be ascertained, a fixed mirror is attached to one of the flanges, which is adjusted so that the spot of light reflected from it is received at the same point on the scale as that from the movable mirror when there is no torque on the shaft.

An electric lamp fixed just above the scale provides the beam of light which is reflected from the two mirrors on the scale successively as the shaft rotates.

A shift of the apparatus relative to the scale is indicated by an alteration of the position of the beam reflected by the fixed or "zero" mirror, and this can readily be adjusted by moving the scale.

The moving mirror is silvered both back and front so that two reflections, one on either side of the beam, are received from it during one revolution of the shaft. The mean of the two readings may thus be taken whatever the position of the zero.

The apparatus may be calibrated directly by applying a known torsion to the shaft and noting the reading of the scale, or by calculation from a knowledge of the torsional rigidity of the shaft and the various leverages and distances involved in the conversion of the twist to the movement of the spot of light on the scale.

The apparatus gives an instantaneous reading of the torsion in the shaft at a particular angular position in the revolution, the angle being fixed by the positions of the mirrors and scale.

The torsion at any other part of the revolution may be obtained by mounting the scale on a circular frame concentric with the shaft and shifting the scale and lamp to the angular position required.

(ii.) The Ayton and Perry Torsionmeter (Fig. 12).—This dynamometer is designed for use in the place of the ordinary shaft coupling, which purpose it also serves. The two halves, one on each shaft, are connected by means of helical springs, three or four in number, arranged in a position approximately tangential to the shaft. When power is transmitted, the drive is taken through the springs which extend under the load. The stretch of the springs allows relative angular movement between the shafts, and this is indicated by a lever arrangement which has the ultimate effect of reducing the distance of a bright bead from the shaft centre. The radial position of the bead is observed against a black disc on which a scale is marked.

The apparatus is calibrated directly or by calculation from the stiffness of the springs and the magnification of their extension which has been employed. Calibration against an absorption dynamometer is preferable if it is thought that the arrangement of the springs adopted is likely to give different calibrations statically and dynamically.

§(4) THORNycroft or Froude Belt Dynamometer.—The arrangement of this transmission dynamometer is shown in Fig. 13. The pulley D, fixed to the shaft of the prime mover, drives the pulley F by means of a belt which
to follow fairly round a curve without affecting the readings, but so held that the wheel always remained vertical. The fulcrum of the lever could be moved to either of four positions such that the pressure on the plunger was equal to, or two, four, or eight times the pull exerted on the frame. The range of the apparatus could thus be varied from 3 to 500 lbs.

The record of pressure and speed was made by pencils on a sheet of paper which were rotated by a roller the motion of which was obtained through gearing from the road wheel.

(6.) The British Instrument. — This dynamometer has been specially designed for the determination of the draw-bar pull of farm implements and the tractive resistance of ploughs working under various conditions.

The pull is transmitted from the plow to the plunger through a link or chain and a piston working in a cylinder. The latter contains a rubber bag containing liquid which is compressed by the piston. This pressure unit is hitched in one of three different ways giving different ratios between the pull and the pressure on the rubber bag. The three hitches correspond to maximum pulls of 300, 600, and 1200 lbs., respectively.

The recorder consists of a British recording pressure gauge. It is connected to the pressure unit by a flexible metallic tube which conveys the liquid under pressure from the rubber bag to a Bourdon pressure tube which actuates the pen mechanism. A needle valve, inserted in the pressure tube, may be adjusted to control the flow of liquid and to damp out excessive vibrations of the pen.

The chart is a circular sheet of paper divided by a series of concentric circles around which the pen travels in an approximately radial direction from the centre outwards with increasing pull.

The chart is caused to rotate by a wheel which rolls over the ground and which is connected to the recording instrument by a flexible shaft and suitable gearing. The circumference of the chart is divided into equal parts each representing a distance travelled of 100 feet.

A second pen records the elapsed time on an annular space at the edge of the chart. A clock in the recorder case, fitted with a cam, trips the time pen at one-minute intervals, and fractions of a minute may be estimated by counting the number of smaller spaces over which the pen has travelled.

The division is accomplished by dividing the annular space by a number of concentric circles and by causing the time pen to travel from the outer to the inner circle in the minute intervals, after which it is again tripped back to the outer ring, its path being practically a radial line.

The recorder is lightly built and is provided with straps by which it is carried by an assistant during a test. It is arranged that
the rolling wheel may either be clipped to the tractor or guided by hand.

From the chart obtained, the draw-bar pull, the distance travelled every six seconds, and the speed during the test may be deduced.

(iii) The National Physical Laboratory Tractor Dynamometer Car.—This apparatus was constructed solely for measuring and recording the tractive effort of farm tractors, for which purpose it has been successfully used. The car employed was a heavy four-wheeled lorry, the rear wheels of which were fitted with speedometer and hand brakes, the latter being operated by a hand wheel from the front of the vehicle. The apparatus was mounted on an extension of the bogie frame carrying the wheels of the trailer.

The pull of the tractor was converted to pressure on a leather diaphragm by means of a bell-crank lever suitably pivoted, the diaphragm being faced on the pressure side with a rubber disc to prevent leakage of the liquid in the diaphragm box through the leather. A flexible hydraulic pipe connected the diaphragm casing to a Bourdon pressure tube operating a pen mechanism, and a record of the pressure was thus obtained on a roll of paper. The latter was caused to move proportionally to the distance travelled by the car, the driving drum being rotated by means of gearing and a flexible shaft from the loading road wheels.

Two other pens were also provided, one operated by a clock in order to give time indications every two seconds, and the other operated through gearing and giving indications of the revolutions of the tractor engine.

The diaphragm box to which was attached the fulcrum of the bell-crank lever, could be adjusted vertically so that the rope or chain connection to the tractor could be arranged horizontally.

In carrying out a test, the brakes of the car were adjusted, and the car loaded with dead weights, until either the engine of the tractor was pulled up or the driving wheels began to slip. The maximum pull of the tractor on the particular surface chosen for the tests was obtained.

(iv) Railway Dynamometer Cars.—Dynamometer cars have been constructed for traction tests on locomotive engines and tractive resistance tests on railway rolling stock. The car usually takes the form of a special coach, the draw-bar pull and buffer thrust being recorded, with the speed, on a paper-covered drum driven through gearing from one of the road wheels.

A most successful car of this type is that designed by Mr. George Hughes for the Lancashire and Yorkshire Railway Company. The various instruments with which this car is fitted enable complete records of the performance of the locomotive to be taken, including draw-bar pull (or push), speed, acceleration or retardation, and buffer pressure of the locomotive.

Other factors influencing the performance are also indicated on the chart by observers.

Considerable care and experience is required in the design of a car of this kind, and the more salient features of the Lancashire and Yorkshire Railway car are here described for the first time by the courtesy of the Chief Engineer of that Company.

(v) The Lancashire and Yorkshire Railway Company’s Dynamometer Car.—The draw-bar pull and the thrust on the buffers of the car are transmitted to two compound springs, one being provided for the pull and the other for the push. Each is made up of a number of independent plates bound together by a pair of buckles at the centre and connected by links at the ends. The link pins can be withdrawn separately as desired, and this enables the number of plates in operation to be adjusted to suit the load hauled, from a single each to the heaviest train, utilizing the full deflection of the springs.

The spring deflection is recorded directly on the record paper without the intervention of levers, showing draw-bar pull above, and buffer thrust below, a datum line.

The external carriage coupling arrangements are standard practice so that the car can be coupled up as readily as any other vehicle. The draw-bar and buffers are connected to a rigid frame which moves each set of springs in one direction only so that the tightness of the same shackle between the engine and the car does not affect their indications.

A compensating beam equates the thrust on the buffers when negotiating a curve.

The draw-bar passes through a friction device which can be brought into operation to take the load off the springs when tests are not being made. The device is also used to absorb exceptional shocks during the last inch of deflection of the springs. A main cross-beam near the centre of the car under-frame forms a foundation for the springs and the instrument table.

The motion of the car is not recorded from the ordinary road wheels but from a special measuring wheel arranged between the leading and trailing wheels of the bogie, so that there is little lateral movement when making curves. The measuring wheel is pressed on the rail by a spring and can be raised or lowered as required. The motion is transmitted to the instrument table by worm gearing and flexible couplings forming a positive drive.

The instrument table carries the record paper drum, the speed gear which regulates the relative speeds of the paper and the train, a distance indicator, a work integrator, a recording and a visual speedometer, a standard electrical clock, and an inertia ergometer.
Tho record paper can be driven at speeds varying from six inches to twenty feet per mile travelled; a counter marks the paper every mile.

The work integrator consists of a disc rotated from the road wheel, and across the face of the disc a roller is moved by the extensions of the springs. The rotation of the roller is therefore proportional to the product of the draw-bar pull and the distance travelled, and this work is continuously recorded on the chart as a serrated diagram, each peak representing approximately 50 horse-power minutes per pair of springs in use. A counter gives the total positive, total negative, or algebraic sum of the horse-power minutes done by the draw-bar, as required.

The speed recorder works on a positive principle, namely, that the distance travelled in a definite time (4 sec.) gives a measure of the mean speed during the four seconds.

(vi.) The Inertia Ergometer.—This was introduced by Joseph Doyen, Chief Engineer of the Belgian State Railways, and is a combination of the Doyen inertia dynamometer (pendulum) and the Ahlbank-Abakanowicz integrating roller. The pendulum is mounted on knife edges and swings in the direction of motion of the car. The tangent of the angle of the pendulum with its neutral position is proportional to the algebraic sum of the force of gravity and the force producing change of velocity (acceleration or retardation). The integrating roller multiplies this force by distance and the result is indicated on the record paper as an inclined line. The change in the ordinate of this line represents the change in the algebraic sum of the potential and kinetic energy per unit mass of the train, when coasting free, the loss of energy recorded is due to train resistance, and is therefore a direct indication of it.

By means of a run made up of alternate haulings and coastings the ergometer provides data from which the work done by the prime mover can be calculated. By combining this information with that of the draw-bar integrator the locomotive resistance, train resistance, total resistance, and acceleration effect of the locomotive can be obtained for any speed.

Curvature of the track is indicated and has been found to account for many peculiarities in the diagrams obtained. Fig. 14 is a general view of the instrument table. The work integrator is shown in the centre foreground; the lever from the draw-bar springs stands up through the central slot in the table and the pendulum lever through the slot on the left. The ergometer drum can be seen to the left of the top of the draw-bar lever. The clock is removed to expose the ergometer to view.

Fig. 15 is a specimen, reduced in size, of the chart obtained for a run of approximately six miles.
DYNAMOMETERS

(vii.) The Swiss Style Railway Car.—Much of the apparatus fitted in this dynamometer car is in many respects similar to that of the Lancashire and Yorkshire Railway Company's instrument. The principal difference between the two car lies in the method of measuring the tractive effort, which in the present instance is by the use of hydraulic gear. Undoubtedly the hydraulic dynamometer has distinct advantages over the spring type, provided it is carefully designed and accurately made.

The pull of the draw-bar is transmitted to a steel plunger working in a steel cylinder, both elements being ground so accurately as to render the use of packing unnecessary. The cylinder is filled with oil by which the pressure is transmitted to the recording instrument, and it is arranged that there is a very slow leakage of oil between the plunger and the cylinder wall in order to provide lubrication for the former and to minimize its frictional resistance.

The arrangement of the pressure unit is shown in Fig. 16. There are two plungers, indicated at A and B, fitting into cylinders which are placed back to back and formed in a solid forging. The draw-bar pull is transmitted to one of the plungers, and the buffer thrust to the other, by means of the crossheads C and D and the rods E and F. The latter are guided by rails suitably supported by a rigid frame. The clearance spaces in the cylinders, behind the plungers, are connected by pipes to a distributing valve, and from there to the recording mechanism.

The recorder consists of two small measuring cylinders arranged in tandem and provided with differential plungers opposed to each other. This arrangement provides that by a suitable setting of the distributor valve the resultant area of the plungers exposed to the oil pressure from the main cylinders may be varied in the ratio of 1:2:3; thus by rotation of the distributing valve it is possible to select either of three scales for recording the load.

A calibrated helical spring is fitted between the two differential plungers and is compressed by their motion. The compression of the spring is a measure of the resultant and force on the plungers and, therefore, of the difference between the draw-bar pull and buffer thrust, and this motion is transferred directly to the record paper by a rod carrying a stylus.

During prolonged runs the slow leakage past the main plungers may cause one of them to touch the base of its cylinder, but before such a condition can arise an equalising valve is brought into operation which has the effect of equalising the pressures in the two cylinders and restoring their central positions as shown in the figures. Fresh oil is drawn into the cylinders from a reservoir, through a non-return valve, when required.

This machine was designed by Mr. F. W. Lancaster for the accurate measurement of the efficiency of worm gearing. A diagrammatic sketch of the apparatus is given in Fig. 17.

The efficiency of modern worm gears for heavy transmission is of the order of 95 per cent, and, under the best conditions of loading and lubrication, as high as 97 per cent. With such efficiencies, separate determinations of the torques in the worm and worm-wheel shafts by any of the methods already described would be liable to give misleading results unless the accuracy of the measurement in each case was within a small fraction of 1 per cent of the true value. For example, in the case of a gear of 97 per cent efficiency, if the torques could be measured separately to an accuracy of 0.2 per cent, the experimental determinations of the efficiency might range from 96.6 to 97.4 per cent. It is evident, therefore, that the ordinary methods of torque measurement in which the error may be much as 2 per cent are quite useless for the purpose, and that a method of much greater accuracy is required. The Lancaster machine measures, in effect, the ratio of the two torques, and the overall efficiency of a worm gear with its bearings can be obtained with an accuracy of 0.5 per cent. Indeed, differences of efficiency due to such causes as changes in the temperature of the lubricant can be easily detected.

Referring to Fig. 17, the gear box is supported in a cradle A in such a manner that it has freedom of motion through a small angular...
about two axes at right angles. The worm is driven by a shaft \( B \) through the intermediate shaft \( C \), the latter being provided with universal couplings at each end. By the same manner the wheel shaft is connected to the bevel box \( E \) through the shaft \( D \) and the universal couplings \( FE \). The load is supported by a bracket \( K \) fixed to the axis \( G \), the axis of the arm being parallel to, and in the same vertical plane as, the worm-shaft axis.

The load is not fixed directly in the bracket but is carried by a slide from which it is hung: by a screw and nut device the distance of the load from the axis of the arm can be varied.

The position of the bracket with respect to the wheel axis being fixed, the moment of the load about that axis is equal to the product of the weight and the length of the arm, and is always the same for the same load.

The moment about the worm axis, however, can be adjusted by means of the screw gear, the reading of the scale on the bracket giving the distance from the weight, from the axis.

It will be seen, therefore, that assuming the gear efficiency as 100 per cent, and the gear ratio as \( R \), the speed of the worm being \( R \) times that of the wheel, the torque on the worm shaft will be \( 1/R \) times the torque on the wheel shaft. The load being the same for each torque, the distance of the weight from the worm axis will be \( 1/R \) times its distance from the wheel axis.

The efficiency of the gear being less than 100 per cent, the load must be moved farther from the axis of the worm in order to balance the gear box against the two torques when running under-load.

The calculated distance of the weight from the worm axis, assuming 100 per cent efficiency, divided by the distance required to produce a balance, gives the efficiency of the gear.

The drive from the worm wheel is taken through the bevel box to the belt pulley \( M \), the latter being of such a diameter that it tends to drive the pulley \( N \) on the driving shaft \( B \) at about 5 per cent higher speed than is established by the bevel and worm gears.

In other words, it is arranged that the peripheral speed of the pulley \( M \) is 5 per cent higher than that of the pulley \( N \).

The belt connecting the two pulleys can be adjusted in tension, over a wide range, an increase in the tension producing an increase in the torque. By this means the pressure between the teeth of the worm and wheel can be made to correspond with the transmission through the box as much as 150 horse-power, it being only necessary to supply the loss of power in the gear and apparatus from an external source developing about 15 horse-power.

This ingenious principle enables prolonged tests to be carried out at a small fraction of the cost which would be involved if the whole power were developed and absorbed.

(ii) Spur Gear and Driving Chain Testing Machine (National Physical Laboratory).—This machine is arranged to measure the difference of the torques of two shafts, together with the measurement of one of the torques separately.

It will be evident that the high degree of accuracy required in the Landesensor machine is not essential in the present machine.

Thus, supposing the true efficiency of a spur gear or chain drive is 97 per cent, and that the determinations of the torque and torque difference are each within 0.5 per cent of their true values, the estimated value of the efficiency of the transmission from the observations may range from 96.9 per cent to 97.1 per cent, which is of a higher degree of accuracy than that obtained by measuring the torque ratio to 0.2 per cent.

Fig. 17 shows the arrangement of the machine. The frame carrying the gears is entirely supported by horizontal knife edges, and both driving and driven shafts are considerably extended and provided with ball-bearing universal joints at each end. Being supported in
this manner, the frame can execute small oscillations in a vertical plane about its neutral position.

The intermediate wheel is rendered necessary in order to secure that the reaction on the frame should be equal to the difference between the torques of the driving and driven shafts, and for this to be the case it is requisite that the shafts should rotate in the same direction.

The first and intermediate gears and the

providing for the torque and its amplitude, readings being taken very slowly.

A Hopkinson-Thring torsionometer is used to determine the torque on the shafts, and in carrying out a test approximately calculates the torque and maintains a constant value, whilst a second observer with the torque measurement is provided. The method of increasing the difference between the gear teeth in the idle as that adopted in the machine. This ensures that only power needs to be supplied from the source. The centre distance of the frame is made adjustable over a wide range to accommodate varying sizes of lengths of chain drive.

During testing the tilting frame is enclosed in a tight case and power to spray the lubricant on the gears being supplied by means of a hose. Such a manner that no control over the lubrication is lost.

In testing spur gears the value of \( T_2 \) on the last gear can readily be determined from the observed data. The efficiency of a pair of gears is given by the equation

\[
\eta = \frac{T_2}{T_1},
\]

where \( T_1 \) is the mean torque of the driving shaft.

The efficiency of a chain is given by

\[
\eta = \frac{\text{Speed of Chain Drive}}{\text{Speed of Motor}}.
\]

In this machine the gear box is arranged in a manner that it is free to rotate in a mean position on the axis of the horse and the torque on the frame of the gear box is maintained and measured. The gear box only be used in cases where the driven shafts of the unit are left to the frame at opposite ends and usually the form of gear box makes them suitable for the apparatus as designed.

The unit under test is fixed in a frame provided with a hollow test barrel axially with the main shafts. The barrel is supported in half-ball bearings on the frame and the gear box can tilt in either direction of the frame being fitted with a cover provided with the usual dashpot, spring, balance weight, pan, and so on.

The two shafts of the gear box are driven by a prime mover and an electromotor respectively, or the latter may be fitted as a dynamometer, i.e. a steady running brake only is used in the transmission end.

The method of test is very accurate than that of measuring the input and output torques for the test.
arrangement, when the efficiency of the gear box is of the order of 97 per cent, no exact results can be obtained, because the errors in estimating the two torques directly affect the calculated efficiency.

Consideration of the two cases will show that in the latter, assuming the accuracy of both torque readings as ±1 per cent, the efficiency obtained will vary from 95 to 99 per cent if the actual efficiency is 97 per cent.

On the other hand, using the more accurate method, and assuming the accuracy of the dynamometer as ±1 per cent, as before, and that of the torque measurement on the gear-box frame as ±2 per cent, the efficiency determination will vary between 96-9 and 97-1 per cent, i.e. a variation of only one-twentieth of the first method. In practice the accuracy of the measurement of the torque of the springs, proportional to the torque transmitted, being indicated by the relative displacement of a pointer over a drum which carries a slip of paper. The position of the pointer at any time during an experiment is recorded by passing a series of high-tension electric sparks through the paper so that the magnitude of the torque may be directly calculated from the known calibration of the springs. A pencil or pen could not be used for the indicator because of the difficulty of balancing the centrifugal forces called into play by the high speed of rotation and also the friction of the pen or pencil on the drum. Alternate torque springs are wound in opposite directions so that the forces produced by the tendency to unwind due to centrifugal action counterbalance each other; with this arrangement it was found that the static and dynamic torque calibrations agreed with each other.

---

The apparatus has been used to determine efficiencies under different conditions of lubrication, and differences due to temperature and quality of lubricant have been observed.

§ (7) AERIAL PROPELLER DYNAMOMETERS.—In order to accurately determine the performance and efficiency of airscrews, two dynamometers have been designed and made in the Aeronautics Department of the National Physical Laboratory.

The problem of the design of such an instrument involves the determination of the air speed relative to the propeller, the torque and the thrust, observations of each being made at the same instant of time.

In the two wholly different forms described below experiments were made on scale model airscrews about one-sixth full size.

§ (8) WHITLING ARM DYNAMOMETER.—A sectional drawing of the dynamometer is given in Fig. 20. The airscrew shaft is driven through flat coiled springs S, the extensions on the rectangular frame can be determined to within 3 per cent.

The apparatus has been used to determine efficiencies under different conditions of lubrication, and differences due to temperature and quality of lubricant have been observed.

When the thrust of the airscrew balances the pull of the spring the lever floats between the stops, but when the thrust is too great or too small contact is made with one or other of the stops and an indication is thus given by means of a galvanometer.

Oscillations in the torque springs due to small irregularities in the driving torque are damped by the oil dash-pot K. This consists of a series of concentric discs, alternate discs being attached to the sleeve carrying the inner ends of the springs and to the drum to which the outer ends are fixed. The oscillations are damped by the fluid friction between the discs.
The apparatus is mounted on a whirling arm about 30 ft. in radius, and the centrifugal force on the airscrew has no component in the direction of the thrust. Certain forces due to centrifugal action are automatically balanced by suitably placed masses.

The airscrew speed is measured by means of the voltage obtained from a small electric generator driven by the propeller shaft, or alternatively by measuring the time elapsed for each hundred revolutions of the shaft. The speed of the apparatus relative to the air is obtained by means of a Dines tube. All electrical and air connections are taken to the central shaft of the whirling arm, from which they are again taken to an observing table when the speeds of the arm and propeller shaft are controlled.

§ (3) Fixed Axial Propeller Dynamometer, for Use in a Wind Channel.—A sketch of this apparatus is given in Fig. 21. It consists of a small electric motor A bolted to a cradle, the ends of which are attached to two hardened steel points bearing in the cups of the "Y" pieces M. These "Y" pieces are rigidly connected to the lower ends of the diagonally arranged wires C, the upper ends of which are supported from the roof of the tunnel by stirrups carrying hardened steel points bearing in the cups D. With this method of support the electric motor is capable, if there is no other constraint, of a swinging motion in the direction of the motor shaft and also of a rocking motion about the axis passing through the points B, B, this axis being parallel to, and slightly below the axis of, the shaft. A spindle arm E, projecting from the underside of the cradle, is connected by a strut and a "C" spring to the top of a spindle clamped to the head of an aerodynamical balance the vertical head of which projects up through the floor of the wind channel. The spindle arm E and the top of the balance arm are encased in a guard which is streamline shape surrounding the strut and "C" spring. A revolution counter driven by the motor shaft and in electrical communication with a bell enables the rotational speed of the airscrew to be measured. To avoid any unnecessary constraints of the moving parts of the apparatus the electrical connections to the motor are made through the mercury cups G. The scale of the model airscrew used with the apparatus needs to be such that the motor with its contiguous parts is completely enclosed in a shell of the model aeroplane body K, and such as to ensure sufficient clearance between the surrounding shell and the moving parts of the measuring apparatus. The body is suitably supported by bars from the sides of the channel.

When measuring torque, the rocking axis BB of the motor and airscrew, which is parallel to the airscrew shaft, is fixed parallel to the centre line of the channel by rigidly attaching the "Y" pieces to the bars L. The brackets at the lower end of the arm E and at the top of the balance spindle are adjusted so that the strut which transmits the load to the top of the balance arm is at right angles to the airscrew shaft. A direct calibration of the apparatus may be made by applying a known torque and weighing directly with the balance.

To measure thrust, the "Y" pieces are detached from the bars L so that the motor and airscrew have freedom to swing in a longitudinal direction about the points B at the upper ends of the wires and the points B of the motor cradle. The brackets on the lower end of the arm E and the top of the channel spindle are adjusted so that the strut F which transmits the thrust to the top of the balance is parallel to the airscrew axis. A strut N, which is held in position with a "C" spring between the bracket O and the cradle and one of the bars L, prevents the motor rocking about the axis BB. The calibration of the thrust apparatus may be obtained by applying a known thrust along the airscrew axis and measuring directly the airscrew balance.

The air velocity in the channel is measured by a tilting manometer.

EDDY VISCOSITY. See "Mechanical Viscosity, Friction," §§ (10), (11), (12).

EFFICIENCIES OF INTERNAL COMBUSTION ENGINES. Table of Ideal Values. See "Engines, Thermodynamics of Internal Combustion," § (40).

EFFICIENCY OF A HEAT-ENGINE. The efficiency is measured by the ratio \( \frac{Q_1 - Q_2}{Q_1} \), where \( Q_1 \) and \( Q_2 \) being the amounts of heat taken in and rejected respectively. If \( T_1 \) and \( T_2 \) be the corresponding temperatures on the Absolute Thermodynamic Scale, we have for a reversible engine

\[
\frac{Q_1 - Q_2}{Q_1} = \frac{T_1 - T_2}{T_1}
\]

Thus the efficiency of any reversible engine working between temperatures \( T_1 \) and \( T_2 \) is

\[
\frac{T_1 - T_2}{T_1}
\]

See "Thermodynamics," § (20).

EFFICIENCY OF RANKINE CYCLE. See "Steam Engine, Theory of," § (3).

ELASTIC CONSTANTS, DETERMINATION OF, AND THE TESTING OF MATERIALS OF CONSTRUCTION

§ (1) INTRODUCTION. — The reasons for the testing of materials of construction are various and depend upon the point of view in which the inquirer approaches the subject.

The designer, in order to proportion the parts of his machine or structure and apply his theoretical calculations, requires to know the physical constants of the materials with which he deals. The aim of the scientific experimenter is to supply this data in order that the theoretical researches in applied mechanics may be applied to the problems with which the engineer is confronted in his practice. Absolute results concerning definite properties of materials form the basis of scientific testing.

The material to be used in the construction of any structure can usually be obtained from several sources of supply and of several grades and prices. The engineer wishes first to indicate to the manufacturer the class of material he needs, and for this purpose he supplies him with a specification containing among other things particulars of the properties required. The design is based on certain values for the physical constants, and these values are the real criterion of the suitability of the material for the purpose for which it is intended. The determination of the constants is usually a slow laborious business requiring considerable skill and scientific ability. Approximate tests have been devised, which are only intended to give a comparative indication of the physical properties of the material. The results expected from these tests are inserted in the specification; in some cases they approximate closely to the scientific tests.

It is, obviously, important for the engineer to be assured that the material supplied fulfills the terms of the specification, and for this purpose he selects sample portions of the material and subjects them to the specified tests. Commercial testing is therefore carried out to determine whether materials conform to the terms of specifications.

There is a further section of the subject which has been given a great impetus in the last few years, viz. investigatory testing undertaken to determine causes of failure of material in actual practice and to improve processes of manufacture and design of machines and structures.

The science of engineering is advanced by a systematic study of failures probably quite as much as by any other branch of research. In investigatory testing, methods are employed to exaggerate certain properties in order to compare them in various materials with ease and certainty. These same properties can probably be studied by a careful analysis of the absolute results obtained by scientific testing, but the process is difficult and cannot be attended with success without considerable practical experience.

I. TESTING MACHINES

§ (2) GENERAL METHODS. — There are certain methods of test which are applicable to all branches of test work. The complexity of the machines employed for these tests depends upon the number of purposes for which it is intended to use them. This complexity is contingent upon

(1) The variety of materials it is required to test.
(2) The kinds of straining action needed.
(3) The form and size of the specimen to be tested.
(4) The magnitude of the forces to be exerted and measured.
(5) The accuracy required in the results.

By limiting the requirements, the testing apparatus can be made of great simplicity. For instance, in a transverse testing machine such as is used for checking the quality of cast iron in a foundry, the test piece can all be of one size, the straining action is always the same (the test piece being broken as a beam), and there is not a great deal of variation of the breaking load. A machine such as this is simple and effective.
Every increase in the requirements adds additional apparatus to the machine. An auxiliary for one purpose will often interfere with the running of the machine for another purpose, thus causing loss of time in making the necessary adjustments for the experiments in hand. Involving great care in the setting of the machine and making it more difficult to handle. It is therefore in the interest of the user to consider carefully the functions which the machine will be called upon to perform, and to limit them to a minimum. In this way increased efficiency is obtained with minimum cost.

The simplest method of testing is by direct loading, and the earlier researches on strength of materials were carried out by this method. Galileo (1638) and Munchenradt (1729) made many tests on a small scale by this means, and where it can still be applied it is the simplest and best method of testing available. Owing to the difficulty of handling heavy loads it is only available for use with weak materials when at the beginning of the nineteenth century the demand came for tests on a larger scale, it was necessary to consider other means of applying the force than by direct loading, and within a few years the three arrangements found in modern testing machines were employed, viz.: (a) Load applied by hydraulic press—no weighing device, but load calculated from the pressure on the ram. (b) Load applied by gearing at one end—weighing lever at the other end. (c) Load applied by hydraulic press at one end—weighing lever at the other end.

In 1873 method (a) was employed by Brunton & Co. for a thin-plate testing machine. The arrangement for arriving at the load was not capable of giving very great accuracy. It was necessary to make no allowance to the load which was deduced from the indication of a pressure gauge, for the friction of the packing of the ram or the cup leathers, and the amount of this friction was extremely variable.

The Whitworth hydraulic testing machine and the 600-ton testing machine of the Union Bridge Company at Athens, Pa., U.S.A., both used the same principle. The 500-ton Olsen compression machine of the Geological Survey and the Bureau of Standards, and the 600-ton Olsen compression tester of the National Institute at Troy both record the load by the pressure in the hydraulic press, but with these machines the pressure is transmitted to a diaphragm whose area is smaller than that of the main ram. The pressure on the diaphragm is measured by a system of levers. Method (c) has been applied to modern testing machines by eliminating the packing and having an accurately fitted ram and cylinder with small clearance. By using oil the slight leakage between the ram and cylinder reduces the friction to a practically negligible quantity.

The evolution of the other two testing machine arrangements, (b) and (c), from the direct-loading method was due to the introduction of the lever. By placing a lever in between the test piece and the load, the amount of dead weight required was reduced by the ratio of the lever arms. This arrangement, although quite suitable for small pieces possessing little ductility, was found to be open to the objection that, on the material stretches, the position of the lever arms could not be adjusted.

In 1877 Capt. Brown constructed a test machine in which the deformation of the cable was neutralised, and the load applied, by means of gearing at one end, while the load was measured by a lever at the other end. The use of gearing was the method of choosing used in America on machines of the lever type. The same arrangement, although common on small machines in this country worked by hand, had not, however, been used on power-driven machines until recently.

Another method of counteracting the deformation of the test piece was applied by Lagerjelm, of the School of Mines at Stockholm, who conducted experiments in 1886 on a 7-ton machine in which a hydraulic ram neutralised the give of the test piece and applied the load, which was measured by weights acting on a knee lever. About the same time, that principle was also employed by Brunnah in the construction of a machine used at Woolwich Dockyard by the late Professor Barlow for some of his experiments on the strength of materials. This method of construction is, however, always associated with the name of David Kirkfield, who in 1890 erected, in London, his well-known machine of 400 tons capacity. The combination of hydraulic ram and lever has since been in common use in machines of many different. The chief principle of these designs lies in the arrangement of the lever or levers and the position relatively to that of the test piece.

Thomasson, in about the year 1872, measured the load on the lever by means of a diaphragm piston with an extremely limited motion, and balanced the load on the piston by a mercury gauge. Millard and

2 Engineering Record, Feb. 1900, ix.
5 Leblanc, Les Métaux, p. 52.
Elaborating on the principles and applications of testing machines, Emory improved upon existing designs by introducing a machine of 150 tons capacity capable of handling pressures on diaphragm pistons. The machine was designed to provide accurate transmission of the load, facilitating precise measurements.

The first essential requirement of a testing machine is accuracy—the load shown by the machine should correspond to the real load to which the test piece is subjected. To achieve this, the machine must be capable of being easily calibrated. This calibration may vary with the machine type; however, it is advisable to have a consistent calibration for accurate results.

Another desirable feature is simplicity, ensuring that the machine can be used efficiently without the need for complex adjustments. Simplicity facilitates easy operation and maintenance, making the machine more practical for commercial use.

To ensure reliability, the testing machine must be able to withstand the rigors of daily use without frequent alterations. Laboratory equipment, in particular, should be designed to handle a variety of conditions to maintain accuracy.

The American Testing Machine, for instance, features a construction that makes it adaptable for various types of tests. The design ensures that the machine can be easily modified to suit different experimental needs.

Modern testing machines, as described by Emory, have evolved to incorporate advanced features such as autographic recording, allowing for the capture of data in real-time. These machines are equipped with a load cell that transmits the load to a microprocessor, enabling the user to observe and record the test results.

In conclusion, testing machines are essential tools in the field of materials science, allowing for the accurate measurement of properties such as strength, elasticity, and stress. The design and functionality of these machines continue to evolve, aiming to meet the demands of modern research and industry.
The various types of testing machine differ in the way in which these requirements are carried out. The first and second parts are usually combined, and the load on the test piece is applied to one end either by (1) a straining cylinder actuated by a pump and accumulator, screw compressor, or oil pump (hydraulic, rotary, or direct driven); or (2) screw gearing driven by hand or by power (such as an electric motor). Screw power testing machines are divided into two general types—the rotary screw and the rotating nut.

The load or force exerted on the test piece is measured (a), more commonly in Great Britain, by a lever or system of levers with weights or a moveable counterpoise forming a weighing apparatus;

(b) by balancing it with fluid pressure acting on a diaphragm;

(c) by measuring the pressure of the oil or water in the straining cylinder;

(d) by calculating the load from the angle through which a weighted pendulum is lifted.

Testing machines using methods (b) and (c) have the advantage that they are cheaper to make than the weighing lever machine, are practically free from inertia forces, and the load is automatically adjusted to the stress. They, however, require very careful attention and calibration, and are considered by the Board of Trade to be undesirable for use when making acceptance tests.

§ 5 Types of Testing Machines.

Lever Testing Machines.—By far the largest number of machines measure the load by the use of a lever. The loading of the lever is affected either by (a) adding separate weights to a scale pan placed at a fixed leverage (i.e., fixed leverage and variable load); (b) having a single jockey which travels along the beam (i.e., fixed load and variable leverage); (c) a combination of (a) and (b).

These arrangements are indicated diagramatically in Fig. 1. With either of the methods the following points must be borne in mind:

(1) The lever during the test will change its position, and in order to secure constant leverage the points of application of the load must lie in a straight line, i.e., the centre of gravity of the moving weight and any knife edges employed must all lie in a straight line or, if the moving weight is hung from a knife edge, the knife edge must travel along that line.

(2) Any addition of weights during a test must be carried out without producing shocks on the specimen. In these machines in which weights are added to the scale pan it is usual to carry this out by a mechanical arrangement such as is shown in Fig. 2.

In some machines the load is measured by the height to which a pendulum bob is raised. This can be considered as a modification of the lever method. Fig. 3 shows how it was employed in the tests described in the British Engineering Standards Association Report No. 53.

It is desirable that, on the same machine, the percentage accuracy of reading the load should be the same with small as with large specimens, and it is therefore usual to arrange modern testing machines so that the same length of scale is equivalent to at least two values of the load. This is carried out either by varying the leverage or varying the weight of the moving poise.

The leverage is varied by providing alternative fulcra. This method is introduced into the Wicksend vertical machine (see Fig. 10A), and consists in providing a third knife edge which can be put in or out of gear. When it is in place, the knife-edge distance is large and the machine is arranged for use with small specimens, otherwise the full capacity of the machine is available. Thus the same counterpoise may represent say 50 or 100 tons for the same travel of the counterpoise along the lever,
ELASTIC CONSTANTS

according to which fulcrum is used. The method of operating the third knife edge is shown in Fig. 4. The three knife edges are in the same line, but the movable support Y for the third knife edge Z is raised so that

press (as shown) or by screw gearing. The following are modern examples of machines which use this principle.

(ii) "Avery" 10-ton Single-lever Testing Machine.—This machine is shown in Fig. 6. A is the weighing lever and B the poise weight of 840 lbs., which is moved by a control screw C. The screw is driven by hand at D through gearing E and F and a belted joint G, which is placed on a line with the fulcrum. The strain of the test piece is produced through worm and spur gearing by means of an electric motor H, whose control is located at J on the standard near to the hand wheel propelling the poise weight.

The indicator J, which shows the equilibrium of the steelyard, is also close at hand, so that the operator has all the controls within easy reach. The free end of the lever plays in a space in the supporting pillar K. Springs are provided to take the shock when the test piece breaks.

The grips for the test piece are shown at L and M; these are provided with attachments for test pieces with either squared or enlarged ends. The upper grip is attached to the lever, while the lower one, which slides in guides in the standard O, is connected to the straining screw P. The second knife edge Q rests on the standard O.

(iii) "Desmons" 30-ton Testing Machine.—In this machine, shown in Figs. 7 and 8, the load is applied by a straining cylinder, the pressure to which is supplied by a patent hydraulic rotary oil-pump. This pump has a variable
ELASTIC CONSTANTS

delivery in either direction whilst being continuously driven in one direction. The drive can either be by direct coupling to an electric motor, as shown in Fig. 7, or by a belt from a countershaft. A similar pump is used for driving the standard jockey weight in either direction; the speed at which it travels can be varied by means of a lever placed in a convenient position.

The machine is supplied with tell-tale devices, for indicating to the operator the functions of the various parts, as well as all the features which are indispensable for accurate work.

(iv.) Breckon's 100-ton Machine.—A photograph of the machine of this type which is installed at the N.P.L. is shown in Fig. 9. The load is applied by a hydraulic ram and cylinder which are placed in a pit below the floor level. A pressure of 1 ton per sq. in. is supplied to the cylinder by a hydraulic pump and accumulator driven by an electric motor. The counterpoise is driven by hand or mechanically by fast and loose pulleys operated from a suitable lifting. The machine seen in the photograph is fitted with alternative system (see § (ii)) giving a short knife-edge distance of either 3 or 6 inches, so that the jockey weight of 1 ton in travelling the full length of the scale can be arranged to give either a load of 100 or 50 tons.

Another feature of the machine is the arrangement which has been added at the

![Diagram](image)

![Diagram](image)

![Diagram](image)

N.P.L. to prevent the jockey weight accidentally running past the end of the scale in either direction. When a considerable number of tests have to be carried out, it is usual for the operator to measure the extension, contraction of area, etc., and enter up his results, while the counterpoise is running back for the next test. It detracts from his attention if he has to be...
continually on the alert to stop the counterpoise at the right time. The gear is shown in detail in Fig. 10, and operates on the belt-throw-over gear. The shaft A operates the gearing for driving the weight along, placed at the end of the beam, and is worked from the small countershaft (not shown) through level wheels B. The striking gear of the countershaft is operated by a shaft C, which has a handle (not shown) on its lower end. A spur gear on shaft A operates a screw D through gearing. This screw is so arranged that it does not rotate but traverses horizontally as the weight is run along the beam. The screw carries a projection E working in a bracket F attached to the striking gear shaft C. Adjustable lugs G and H are fitted on to this projection and are arranged so that when the counterpoise reaches the extreme end of its travel, in either direction, one or other of the lugs G and H will rotate the striking gear shaft and throw the driving bolt on to the house pulley of the countershaft. The lugs can be adjusted so that, for any series of tests, the counterpoise will be stopped at any predetermined position along the beam. A photograph of the gear is given in Fig. 10a.

![Diagram of the machine](image)

Fig. 9.

(1) only one lever is required for a 500 to 1 leverage, and (2) by an ingenious arrangement, the ram, lever, and weights are all at one end of the machine. It is thus a simple matter to adapt the machine to take test pieces of any length.

The test piece T is held at one end in the framework of the machine A, and at the other pulled by the short arm L of the lever, to which it is connected by a crosshead and long bolts, shown in the diagram by a connecting rod EF. At the end of the long arm of the test piece,
leaver hangs a scale pan W. The central fulcrum of the lever G rests on the end of the ram C, so that, as the test piece extends, the test piece is pulled from the main crosshead V by four rods (two shown in plan as T₁ and T₂), these rods are connected vertically in pairs by crossheads U₁ and U₄ and pull through knife edges C₁ and C₂ on to a large U-shaped block Q, to which the lever Q₄ is rigidly attached. Block Q has two openings in it, through which the crossheads U₁ and U₄ pass. The horizontal line through C₁ and C₂ passes through the axis of the test piece.

The whole system of rods and crossheads hangs from the ram crosshead at N₁ and N₂ on the traverse bar OO. The block Q hangs from this bar by the knife-edge links P₁, P₂ (the knife edges being in the same line as C₁, C₂), its balance being adjusted by the sliding weight S.

In the middle of the block Q the knife edge b is fitted; this bears against a steel face a forming part of the ram crosshead. This knife edge is 3 mm. lower than the line of the others. Thus the ram coming out applies a load to the test piece through the block Q, knife edges C₁ and C₂, crossheads U₁ and U₄, and the rods T₁ and T₄. As the knife edge is 3 mm. out of line with C₁ and C₂, a bell-crank lever is formed, the small arm of which is 3 mm. and the long arm 1500 mm., i.e. the distance the scale pan is away from the knife edge.

It is clear that the length of the short arm of the lever (3 mm.) cannot be directly checked with sufficient accuracy, a contrivance arrangement is therefore provided consisting of a knurled lever f₄ having a fulcrum on the frame K and a ratio of 10 to 1. The knife edges on...
ELASTIC CONSTANTS

The arrangement of machine which is largely used in America is shown diagrammatically in Fig. 14. The straining mechanism is of two types — the rotating screw and the rotating nut.

With the rotating screw machines, the pulling screw passes through nuts which are fastened to the pulling head A. The screws are keyed to and rotated with the main gears through bearings in the cover plate, thus moving the head up or down.

In the rotating nut type of machine, bronze nuts are fastened in the main gears and rotate with them, pulling the screws, to which the head is attached, up and down. The gears rest on long pedestals bolted to the base plate of the machine, and in these pedestals are fixed which prevent the screws from turning.

The thrust, in each case, is taken on the underneat side of the cover plate by ball or roller bearings. The rotating nut machine usually requires a pit or opening in the foundation for the screws which project below the base line of the machine.

The weighing apparatus consists of a weighing table C, levers D₁ and D₂, and a graduated beam B. For tensile strain there is also a weighing or top head F and two weighing the nuts against the bed-plate G is taken by ball thrust washers.

(iii.) Weighing Apparatus.—The weighing mechanism is essentially the same as that of a platform weighing machine. The load on the test piece, applied by the straining mechanism, is communicated to the platform E either directly in a compression test, or through the medium of the upper steel plate B (to which one end of the test piece is wedged) and column A in the tensile test.

The platform rests wholly on three main levers F so constructed as to act as a single lever, and any pressure on it is transmitted directly to them. The knife edges of only one of these levers are shown in the figure.

A second multiplying lever F₂ is placed above and parallel to the lever F, and is connected to it by a stirrup J₂. The reaction of the lever F₂ is taken at K on a strong iron framework which is secured to the gear box of the machine by a diagonal bracket. This framework also holds the support H for the fulcrum of the graduated steel yard G₁, to which the load is transmitted from lever F₂ by the link n.

A cylindrical weight W, which runs on a screw, adjusts the zero of the beam, while a poise y, which travels on wheels, balances the
load applied. The steelyard is graduated up to 100,000 lbs., and an additional weight on the end of the lever adds a further 100,000 lbs.

(iv.) Horizontal Compound Lever Machines.—For testing long pieces, a horizontal testing machine is essential. In order to obviate the difficulties introduced by the small knife-edge distance of the Werder machine, multiple lever arrangements are used. A ball and crank lever is adopted to convert the horizontal force into a vertical one, and this is combined with the weighing lever, either with or without the introduction of intermediate levers.

The arrangement of two machines of this type is given in Fig. 16.

(v.) Large Horizontal Machines.—In order to carry out tests on built-up structural members of a practical size, machines of large capacity are required, and for this purpose no machine of less than 300 tons is of much use. Excluding chain testing machines, the best examples of large horizontal machines built in this country are:

Kirkaldy's machine of 400 tons built in 1868.

The 300-ton machine of the Conservatoire des Arts et Métiers at Paris built by Messrs. J. Buckton and Co. in 1904.

The Avery Machine² of 760,000 lbs. installed at Birmingham University in 1909.

¹ Engineering, Sept. 2, 1904.
² Engineer, May 21, 1909.

The Avery Machine has a ram K at one end and the lever system D at the other. The heavy cast-iron bed XX has substantial standards HH at either end whose tops are connected by horizontal columns YY with the distance,

![Diagram](image-url)
of about 40 feet, between them without intermediate support. There is therefore a clear span along the top and sides, enabling heavy test pieces to be lowered in position by the traveller running overhead. To one

Diagram of Greenwood and Batley’s Horizontal Testing Machine

Diagram of Buckton’s Horizontal Testing Machine

Fig. 16.

standard the cylinder L is bolted, while the lever system is fixed to the other.

The load is applied by hydraulic pressure. At Birmingham the town pressure of 100 lbs. per square inch is available for low load tests and gives a total thrust of 35 tons. For the full capacity of the machine an accumulator supply of ten times the pressure is used. The diameter of the ram is 32 inches and its stroke 60 inches. The main cylinder L, bolted to the standard, forms part of the machine frame, by means of four notched hooks N, sliding in the frame of the machine, which are fixed to the head of the ram and into which the crosshead No. 2 is keyed in any desired position. One end of the test piece is fixed to the crosshead No. 2 and the other end to the crosshead No. 3 for compression and the crosshead No. 1 for tension. Crossheads No. 1 and No. 3 are suspended from knife edges on the top of the frame Y and are connected by tension rods P, P’, which, when crosshead No. 3 is in use, transmits the load to the lever system through crosshead No. 1 and the main link BB. The main link BB pulls on the top knife of a bell-crank lever through a hardened steel bearing block Q. Thus, for compression, the load is communicated to the weighing apparatus from the ram by way of (1) sliding hooks N, N, (2) travelling crosshead No. 2, (3) the test piece, (4) the floating crosshead No. 3, and rods P, P’, (5) crosshead No. 1, and (6) main link B.

The weighing apparatus consists of a bell-crank lever A whose principal knife edge K, 6 feet long, thrusts against a plate fitted in the bed of the machine. The load is supplied by the main link B on to a knife edge K, similar to the principal knife edge but a short distance above it and forming with it the short arm of the lever. The intermediate lever C and the main steelyard D are at right angles to the axis of the machine. The former has its fulcrum on a substantial casting E, fixed to the bed of the machine.

and the main ram K, having an internal diameter of 20 inches, moves over an auxiliary fixed ram M whose function is to provide for the return of the main ram after the test is completed. The main ram is driven forward by admitting low-pressure water behind the fixed ram. The load on the ram is communicated to the travelling crosshead No. 2 and the load from the bell-crank lever is transmitted to it by the link and shackle Q, T, while the latter has its fulcrum supported by a column H on the side of the machine. The split counterpoise system (see S, S) has been adopted in order to obtain an open scale for small loads. In this case it is divided into seven equal pieces giving, separately, a
maximum load of 100,000 lbs., and when combined the full load of 700,000 lbs.

The counterpoise can be moved by hand or operated mechanically through a screw, and all the movements are controlled by one operator at the lever end of the machine.

§ (8) DIAPHRAGM MACHINES.—Diagrammatic sketches of diaphragm machines are given in Figs. 19a to c. Fig. 19a represents the Thomassett machine, constructed about the year 1872, in which the load is communicated through the test piece $t$ to a lever $l$, the end of which bears on to a diaphragm $d$. The pressure of the lever on the diaphragm is balanced by fluid pressure, the amount of which is measured by a gauge.

The Maillard machine (Fig. 19b) is similar to that designed by Thomassett except that the intermediate lever is dispensed with, the pressure being taken directly on the diaphragm, which is consequently much larger. The Maillard principle is adopted by Messrs. W. H. Bailey & Co. in their 5000-lb. Ster-Hydraulic tester, and is a very convenient arrangement for small testing purposes. The

---

Lebasteur, Les Métaux, p. 52.
load is applied to the back of the diaphragm, and the pressure in the diaphragm chamber is measured by a pressure gauge or mercury column.

**Fig. 19a.** - Diagram of Emery Machine.

Emery machine, the first example of which was completed in 1879; it is really a compound lever machine with a hydraulic lever introduced between the test piece and the weighing apparatus. The pull of the test piece is communicated to a diaphragm D. It is transmitted from this to a reducer R, the pressure on which is balanced by the lever system.

6. **Emery Machines.** - The first Emery machine owes its origin to the United States Board for testing steel, iron, and other materials, who entered upon their work in 1875. One of the most important actions of the Board was the acquisition of an 800,000-lb. testing machine which they ordered from A. H. Emery of New York. This was completed in 1879, and is one of the largest and most accurate testing machines in the world. Unwin, after inspecting an Emery machine, said: "The merit of the Emery machine was that, while it had been made as much more delicate and sensitive than an ordinary machine as a chemist's balance was in comparison with a grocer's scales, this result had at the same time been obtained by means which rendered the more sensitive machine less liable to injury, less liable to wear, and less liable to get out of order, than the ordinary machine."

The principal peculiarities of the Emery machine are: (a) An arrangement of hydraulic chambers and diaphragms able to receive large pressures and shocks without injury and to transmit them to a convenient point for measuring and recording.

(b) The replacement of knife edges with thin blades of steel. These were introduced to "absolutely eliminate friction and to preserve indefinitely the fulcrum intervals or distances precisely as they were adjusted, and to resist and transmit all the pressures and shocks to which the fulcruums are subjected without in the slightest degree impairing their sensitiveness or durability."

Numerous machines have been made in the United States since 1870 on the Emery
ELASTIC CONSTANTS

principle. Figs. 20 and 21 show particulars of the more important working parts of a 300,000-lb. vertical Enerly testing machine; detailed drawings are given in Mr. Towne's paper.

(iii.) 300,000-lb. Enerly Machine (Figs. 20 and 21). Straining Gear.—A tension test piece A (Fig. 21) is shown between the shackles U and L of the machine. The upper shackle U is attached directly to the ram P of the straining press, which is carried by two main adjusting guide screws M rising from the bed of the machine F. The vertical adjustment is effected by means of the nuts N, which are geared together and are rotated through a shaft and bevel gearing by a handle X.

The fluid pressure is conveyed to the ram by the pipes T₁ and T₂, which have swivel joints to allow for adjustment of the straining cylinder.

(iii.) Hydraulic Lever.—The lower shackle L is secured to a yoke consisting of two blocks H and B connected by four steel bolts W. This yoke the hydraulic support S is placed between the two beams G₁ and G₂. Thus the load is transmitted directly to the hydraulic support through the yoke and beams; the upper block H acting on beam G₁ for compression and the lower block B communicating the tensile load through beam G₂.

The yoke is secured in its proper position by flat plate springs I which hold it steady laterally while leaving it free to move vertically through the small range desired. The hydraulic support S (Fig. 21) is shown in detail in Fig. 20 and consists of a piston D which can move vertically 0.001 inch in a fixed ring and base block (N and K). A space of 0.1 inch is allowed between the piston D and the ring N.

The lower surface of the piston and the upper surface of the base block are turned with annular grooves and are lined with soft sheet brass 0.005 inch thick. The linings form a seal by being interlocked as shown in the diagram. The piston D, while permitted to move vertically, is secured against lateral motion by an annular diaphragm V at its upper surface, and the exposed portion of the working diaphragm or upper portion of the brass seat at its lower face, which acts as a flexible hinge or joint. The seat is filled with alcohol and glycerine or refined benzene oil, and the load when applied to it is transmitted to a smaller hydraulic chamber or reducer R (Fig. 19b), containing a similar thin film of liquid, where it is balanced by the lever weighing apparatus.

(iv.) Weighing Apparatus.—The maximum load of the machine is thus reduced to a maximum of 10,000 lbs. on the reducer, and this is all the load that is conveyed to the fulcrum plate of the main lever M (Fig. 19c) of the weighing apparatus. Thin pieces of tempered steel are used instead of knife edges, and are forced, under a pressure of about four times the working load, into the pieces that connect. The relation of the beams, which have a total multiplication of 20,000 to 1, is shown in the figure. The total reduction of load is 600,000 to 1, so that very small weights are all that are necessary to keep the levers horizontal.

(v.) Calibration.—The hydraulic support is tested with known loads, applied by a "nating machine," up to the maximum capacity of the Enerly machine. The exact weight required on the weigh lever to balance a known load on the machine is thus found by actual test, and the pieces are carefully adjusted in accordance with this calibration. The nating machine is a carefully constructed dead-weight loading appliance. The weight was produced from standard weights accurately adjusted at the Bureau of Standards, Washington.

§ (9) MACHINES WITH NO WORKING DEVICE. — Machines in this class are those in...
Each installation consists of three main parts:

(1) The press or actual testing machine P,
(2) The oil pump for producing the pressure (C),
(3) The pendulum dynamometer D for measuring the load from the oil pressure in the pressure cylinder.

(ii.) The Press.—The press is fixed to the top part of the machine, and the movable cradle carrying the upper grip is freely suspended from the ram by two rods connected by a crosshead which rests on the top of the ram. The bottom of the cylinder of the press is held rigidly to the base of the machine by four round columns, which are made heavy enough to carry the superstructure and the maximum load without deformation.

The base itself does not take any of the load applied to the test bar T, it is required merely as a support for the machine and to raise the working parts to a convenient height above the floor level. It is made in the form of a hollow iron casting with an opening in the front for the recovery of the fractured test pieces.

The ram of the press is fitted in the cylinder with such precision that no collar or cup leather is required to ensure a sufficiently oil-tight working. The small amount of play which the ram has in the cylinder allows a slight percolation of oil to take place between them; this makes the movement of the ram in the cylinder very easy, eliminating friction and allowing an exact measurement of the total load to be made. The ram can be rotated by a handle, so that by occasionally moving it through a small angle the formation of ridges, etc., is avoided.

(iii.) Oil Pump.—The press is operated by oil pressure produced by a high-pressure pump (C, Fig. 22) driven by an electric motor from a countershaft (for small machines a hand drive can be employed). The arrangement of suction and delivery of the oil is such that if all the valves are kept closed the oil is automatically short-circuited back to the reservoir, which is carried on the pump stand. There are also returns for the oil to the reservoir from the top of the cylinder due to leakage,

owing to the variability of the friction caused by the ram packing. This objection has now been overcome in the machine constructed by Messrs. Alfred J. Amsler & Co., by using oil as the fluid together with an accurately fitted ram and cylinder with small clearance, thus eliminating the packing friction.

(i.) Amsler Testing Machine.—A 50-ton universal machine of this make is shown in Fig. 22,
and for the released oil from under the ram.

Water pressure may be used to work the machine by making arrangements for transforming into oil pressure for working the press.

(iv.) The Dynamometer

Apparatus.—The measurement of the load is made by means of a pendulum dynamometer D. The oil from the high-pressure pump is admitted to the straining cylinder through the dynamometer, so that the actual pressure in the cylinder is shown by the pointer which is operated by the dynamometer.

The pendulum dynamometer is a modification of the dead-weight gauge, which is used for calibrating pressure gauges, the pendulum arrangement being used to automatically balance the load on the plunger, as shown in Fig. 23.

The oil pressure is applied to a plunger P, which is kept slowly revolving during the test by the pulley Pp, from which it is transmitted to a yoke Y connecting two vertical rods G1, G2. The tops of these rods are attached through a ball-bearing coupling to a short block lever H, which is rigidly secured to a shaft J mounted in ball-bearings in the manometer frame. The depression of the block H by the pressure causes the heavy pendulum B to be deflected until it assumes a position of equilibrium. The point of suspension C of the pendulum can be altered so as to increase the sensitiveness of the machine, the connection to the recording gauge being adjusted at the same time.

The arm and rod A attached to the pendulum operates a pointer on a dial and the dynamometer is also provided with an automatic recording apparatus R.

As a rule each testing machine is accompanied by a pump and separate dynamometer, but it is possible for several machines to use a single pump, if worked in conjunction with an air accumulator, and a separate dynamometer for each machine.

For machines of large power, i.e. 300 tons and upwards, Amstol's measure the load by the extension of the columns which carry the top shackle. As these columns extend under the load, they are made to operate a piston in a cylinder. The shapes of the piston and cylinder are so designed that a small relative motion between the two causes a large displacement of the oil which fills the clearance separating them. The displacement of this oil is made to work an indicator which is calibrated in terms of the load.

§ (10) Torsion Testing Machines.—Many universal testing machines of the lever type are fitted with a special shackle for applying torsional stress, as illustrated diagrammatically.
in Fig. 24, in which the torque is applied by a worm and worm wheel A and measured by running the Jockey weight B along the lever arm C. It is usually, however, more convenient to use a separate machine, and Fig. 25 shows a machine of 250 pounds-foot capacity, made by Messrs. J. Buckton & Co., embodying the method of test mentioned above.

Fig. 21.

Fig. 22.

Fig. 23.

Fig. 24.

Fig. 25.

Fig. 26.

Fig. 27.

Fig. 28.

The twist is communicated through the test piece to the other jaw on which a weighted pendulum is attached. The resistance to deflection of the pendulum causes a torque to be applied to the test piece, and the angle of the deflection of the pendulum is a measure of that torque. The history of the test is recorded autographically on a chart attached to a drum which is secured to the jaw which is moved by the gear wheel. The deflection of the pendulum moves a pencil, which is secured to it, over a guide curve fixed to the frame of the machine in such a way that the movement perpendicular to the plane of rotation (that is, the height of the curve) is a measure of the torque, while the length of the curve is proportional to the angle of twist of the test piece.

The two machines described above are typical of all of the methods employed for torsional testing machines.

§ (11) **Transverse Testing Machines.**—Although a transverse testing shackle always forms part of a universal testing set, most testing machine manufacturers supply special machines particularly suited for testing cast-iron by cross-breaking. These machines combine cast-iron foundry bars to be tested rapidly, and give reliable information as to the mechanical properties of different mixtures.

Such a machine, supplied by Messrs. W. H. Bailey & Co., Ltd., is shown in Fig. 27. It is suitable for test bars up to 2 in. deep, 1 in. thick, and 30 in. between centres, and has a maximum capacity of 1500 lbs. An upward force is applied to the centre of the beam by means of a screw, turned by a hand-wheel, lifting a central shackle. The reaction is taken on the beam by two end supports and also on the lever near to the fulcrum. The load is balanced and measured by running the counterpoise along the lever while the deflection is obtained from the movement of the screw which applies the load.

§ (12) **Bars for Holding Test Bars.**—As much care should be bestowed on the design of
ELASTIC CONSTANTS

the grips for holding the test bars as on any of
the other essential parts of the testing machine,
if accurate results are required. It is import-
nant that these should be so designed that the
resultant of all the forces acts along the axis
of the bar, for, if this is not done, the amount
of the ultimate load is affected.

The usual method of ensuring that this
condition is fulfilled is by arranging for some
form of spherical or arrester seating between
the test piece and the connection to the
testing machine. The principal objection to
most of these seatings is that they have no
protection from dust, scale, or other small
pieces which are apt to be scattered by the
test piece on fracture.

In the 100-ton Bantam machine (see § (6))
large hemispherical pieces, \( H_1 \) and \( H_2 \), are
arranged in the top and bottom holders, and
these pieces the special attachments are
fixed for test pieces of various kinds.

(i.) Tension Shackles—Pin Grips.—Fig. 28
shows the oldest method of holding the ends
of plate specimens. A hole is drilled at each
end of the test piece for a steel pin \( A \), and the
pin is driven in to hold the specimen in
position. The relation of the size of the pinhole
and the size of the heads of the test piece to the
reduced section is such that the specimen always
breaks in the reduced section. This form of holder
is one of the best for small specimens, provided
care is taken to ensure that the
pinhole is accurately on the axis of the
reduced part of the test piece, otherwise the
stress across the section is not uniform and the
specimen tees from the edge when the stress is greatest.

(ii.) Wedge Grips.—The ordinary method
adopted for holding specimens of ductile
materials is between two wedges with roughed
surfaces, as illustrated in Fig. 29, but it does not
necessarily ensure that the line of pull is axial.

In order to obtain the best results with this
method the following points must be borne
in mind:

(1) The position of the wedges in the head
and of the test piece in the wedges.

Fig. 29 (A) shows a sectional view of the
testing machine head with the wedge grips
and test piece in position. The wedge grips are
bearing their full length against the head and

the specimen is bearing for the full length of the
wedge grips, and this is the correct condition.

Fig. 29 (B) shows the position of the wedge
grips when the specimen is too thin, and while
the test piece bears the whole length of the
wedge grips, the wedge grips are not bearing
their full length against the head. In this
case liners are used to keep the wedges back in
their proper place, as in Fig. 29 (C), although
to obviate this difficulty most testing machines
are supplied with pairs of wedge grips suitable
for various ranges in the
thickness of the plate.

If the specimen does not
bear for the full length of the
wedge grips
(Fig. 29, D)
there is a tendency,
the application of the
load, for the
end of the
specimen to be
and a
force to be ap-
plied to the head
which may split
it.

(2) The tendency for the
wedges to grip
the test piece more on one edge than the
other.

This arises if the specimen is thicker on
one side or through want of proper adjustment,
when the holders for the wedges are split and
separate from the head, as in the Bantam

![Fig. 27](image)

![Fig. 28](image)

![Fig. 29](image)
100-ton machine (Fig. 30). To avoid this difficulty Messrs. B WEISS supply wedges with a round face. In Fig. 31 (A), C are the round-faced wedge grips contained in the shackles S. Another method for securing proper alignment is a form of ball-socket liner shown in Fig. 31 (B).

The shackle round faced wedge grips for flat or plate specimen

![Diagram of shackle with wedge grips](image)

For round or square ductile pieces the wedge grips are provided with serrated V-grooves, as shown in Fig. 31 (C).

The ends of the specimen are usually enlarged, as shown in the sketch, but with mild steel or iron this enlargement may be dispensed with.

(iii) Self-aligning Grips.—When testing brittle materials or for accurate experiments the alignment of the specimen is especially of importance. It is used in these cases to use circular test pieces with the ends to fit special spherical seated holders. Fig. 32 shows various methods of machining the test piece and attaching to the shackles.

Attached to Spherical Seating in Testing Machine Shackle

![Diagram of spherical seating](image)

(iv) Every 10-ton Shackles.—The arrangement of Avery's 10-ton shackles is shown in Fig. 33. The holder M is attached to a link hinged from the beam of the testing machine by a second link. This holder consists of a forging machined to take a spherical seating A on which the pull of the test piece is taken through a solid steel stem B and nut C. The nut is screwed at N to take speci - men holders of various sizes. Two forms of specimen holder are employed, viz. (1) for headed test pieces D and (2) for screwed test pieces E.

The shackle is also arranged for use with wedges. For this purpose the nut, stem, seating, and bolt L are removed and wedges are inserted, which bear along the surfaces M1 and H1. A handle works in the bearing K, and is arranged with lugs which move both wedges up or down at the same time. This facilitates gripping of the specimen and enables tests to be carried out rapidly.

The top holder, for connection to the lever, is shown in the figures. The bottom holder, attached to the same-straining rod, works on exactly the same principle; a slide, however, is moved by a handle to parallel the vertical testing machine guides. Both holders are shown in the drawing of the testing machine in Fig. 6.

The shackles given in Fig. 34 were designed by the author for tensile testing, more particularly for use in experiments for the determination of the elastic limit and elastic modulus. They consist of a bolt A with a spherical nut B on one end and a holder for screwed or headed test pieces on the other. The nut bears on a spherical seating G, which fits into the shackle of the testing machine. The spherical seating is kept free from dirt by being closed in at the top by a plate E and at the bottom by a piece of wash-leather F, which fits round the bolt. The wash-leather, although forming a dust-proof cover, allows free movement of the nut and bolt on the spherical seating. The space in the bush is filled with vaseline. These shackles have been in constant use and have been found to give every satisfaction.

(vi) Grips for Testing Ropes.—The gripping
ELASTIC CONSTANTS

1S5

of ropes or cables requires considerable care in order to obtain reliable results; it is important that the grips should not damage the ends of the rope, otherwise fracture will occur in the sockets.

The tests are more conveniently carried out in horizontal machines, where there is plenty of available length, than in vertical machines. Serrated wedges (Fig. 35) are used for gripping both wire and hemp ropes, and, to prevent them from being damaged, wooden straps of a suitable thickness and length are placed between the grips and the rope. In order to seize the rope over a considerable length these special wedge grips are made very long.

Where only vertical machines are available a satisfactory way of holding wire rope for tensile tests is to use conical dies in the shackles and seal the ends of the wire in them, as shown in Fig. 36, with a low melting-point alloy. The wire is first tightly bound with fine wire at about 5 in. from each end, the end strands are then opened, bent over, and tinned. The rope is next set centrally in the dies, with a little fire-clay, and a hard alloy of lead and antimony run in forming a solid end.

For hemp rope and small cables a method which is largely used is to splice an eye on to each end and test by placing a steel pin through the eye. A more reliable method is to roll the ends round specially prepared helically grooved drums and clamp them. Such tools are supplied by Messrs. Tinus Olsen Testing Machine Co., in the United States of America, or Alfred J. Amsler & Co. (Switzerland); they are costly to build, but give accurate results in testing such materials.

(vii.) Grips for testing Chain in Tension.—For testing separate chain links or complete chains a piece of steel bent into U form is passed through each of the end links. The open ends of the U-pieces are then gripped in the flat wedges used for testing flat bars (see Fig. 37).

Where it is necessary to carry out a considerable amount of chain testing, blocks to suit the various sizes of chain are provided, which fit into the heads of the testing machine GH (Fig. 38). By means of these blocks sections of a chain can be tested under a
ELASTIC CONSTANTS

proof load: this is not possible with the U-hook method.

(vil.) Compression Shackles. — Spherical shackles for compression tests are necessary for accurate work. These either rest on the lower shackle or hang from the upper shackle of the testing machine. Care must be employed in using any of these arrangements to ensure that the axis of the test piece is in line with that of the bearing blocks and testing machine.

Fig. 39 shows a ball bearing block arranged to fit the upper crosshead of a universal testing machine; this allows for free motion in all directions.

(ix.) Transverse Test Tools. — Figs. 40a and 40b show two types of shackles for transverse testing. Fig. 40a indicates the roller bolster supports and Fig. 40b the arrangement adopted with the Buckton vertical testing machine. In the latter method it will be noted that the pressure is applied in halves, at $W_1$ and $W_2$ giving a small central span $D$ of uniform bending moment. The object of this method is to reduce local crushing of the test piece $T$. In both arrangements the standards $A$, $A$ can be adjusted to graduations on the beam $B$ to give different lengths of span $L$.

As timber is not homogeneous, four-point loading is usually adopted (Fig. 41). This gives a large span over which the bending moment is uniform and in which the beam theoretically bends in the arc of a circle. Fig. 42 is a photograph of these shackles fitted to a 10-ton Buckton testing machine.

The following points in regard to apparatus for transverse tests should be observed:

Rocking supports should be used at the ends of specimens.

Metal plates should be provided, if necessary, to prevent a high intensity of pressure under the point of loading or at the supports.

Deflection meters or deformeters should not be attached close to the points of application of the loads.

If deflections are to be observed, it is advisable that the rate of loading should be such that the readings can be taken while the load is being continuously applied. If a stoppage is unavoidable, the time intervals should be constant for the test.

(x.) Shear Shackles. — There are two methods of applying a shear stress to materials, one by a torsion test and the other by direct shearing or punching. The torsion formula only holds for perfectly elastic bodies, and if it is used for the breaking stress...
a figure greater than the real shearing stress is obtained.

Various methods for direct shear are in use, but with these the shear is always accompanied by a certain amount of bending and compression.

(xii.) Tests of Bar and Plate. — Fig. 43 indicates a shear test tool for round specimens. The specimen A is clamped to a block B and, with the testing machine adjusted for compression testing, the load is applied to the shearing tool C. The test can be arranged so that the specimen is broken in either single or double shear. The dies D, as well as the shearing tool, are made of tempered tool steel ground to an edge. Provision is made for wear of the tools, and they are inserted in such a manner that they can be easily removed when necessary for grinding.

A similar method can be used for flat plates, the form of the shearing tools and dies requiring slight modification to that shown in Fig. 45.

(xiii.) Test of Very Thin Plate. — An arrangement for shear tests on very thin plates or slices from a bar, used at the N.P.L., is shown in Fig. 44. The test piece P is placed in a die D having a hardened steel facing F. A hardened steel plunger P, with a long bearing in the die, is placed on the test piece. The hole in the facing (d) is slightly taper (the figure is exaggerated), and the end of the plunger (d) is made a good fit in the hole.

The gear is placed between the compression shackles of the testing machine and the load measured, which enables the plunger to push a hole through the test piece.

If \( t \) = the thickness of the test piece and \( W \) = the load; then the shear stress = \( \frac{Wt}{dp} \).

(xiv.) Test of Timber in Shear (see section on timber tests, §127).

(xv.) Torsion Shackles. — The easiest way of holding a torsion test piece in the testing machine is to have enlarged ends, either square or round, with two keyways cut in them (Fig. 45).

§13) Calibration of Testing Machines. — The only satisfactory method of calibrating the readings of a testing machine is by using dead loads through the full range, such as in

![Diagram](image-url)

Fig. 45.

The end of the lever is carefully constructed, rest on knife edges in a double chair \( C \). The load \( L \) itself rests on the weighing table \( T \) of the machine. A single chair \( C \) is placed on the other knife edges and forms the fulcrum of the lever; the upper shackle \( C \) of the machine is brought down on to this chair. A leverage of ten is generally adopted for calibrating machines up to ten
tions capacity, and a leverage of twenty up to fifty tons capacity, which is the maximum to which this method of verification is usually carried.

Other methods of checking are as follows:

(i) By a standard test bar made of steel whose modulus of elasticity is known by previous experiment. A test piece is turned to fit the testing machine, and of such a size that when the maximum load is applied to it the limit of proportionality of load to extension will not be exceeded. An extensometer is fitted to the test piece, and readings of it taken at various loads shown by the testing machine indicator. These readings are then compared with those calculated from the modules of elasticity, and a verification of the testing machine scale obtained. This method is difficult to carry out except by persons skilled in such work.

(ii) With Crashers.—These are cylinders of copper whose diminution in length with load is known. A series of crashers are loaded in the compression apparatus of the machine with various values of the load, which are noted from the machine indicator. The actual forces exerted are deduced from the diminution of length of the crashers, and these are compared with the indications of the machine.

(iii) By a Series of Tensile Test Pieces.—These are made in duplicate and of varying diameters, so that the largest test pieces will take nearly the full capacity of the machine.

They are all turned out of the same bar of homogeneous material, and one series is broken in the testing machine to be calibrated, and the duplicate series tested under the same conditions in a machine whose accuracy is known. Both methods (ii) and (iii) are simple, but are not available for a greater accuracy than about 0.2 per cent.

(iv) An Improvement of the Copper crasher method has been suggested by Schule and Brunner, who used wood in the form of slabs of small thickness (2 to 4 cm.) as crashers.

Wood has the unique property of offering the same resistance to crushing whether treated as cubical or thin slabs. This method dispenses with all measurements of deformation which necessitate the use of instruments of precision, and by selecting wood well dried and free from flaws, an accuracy of 1 per cent can be obtained.

Messrs. Schule and Brunner found that the wood of Ceylon is the most suitable owing to its regular structure. Five or six pieces of wood of each cross-sectional area are tested in a standard machine as well as in the machine which is under calibration.

(v) With a "Stabilizing Box."—This is an instrument supplied by Messrs. Alfred J. Anstis & Co. for quick and accurate checking of testing machines. It is essentially a hollow test bar whose strains under loading are measured by its diminution or increase in volume. It is filled with mercury, and has a horizontal capillary, which is also partly filled with mercury, attached to it on one side, and a micrometer, working a plunger in and out of the box, on the other side. When the instrument is stressed axially, the position of the mercury in the capillary tube is altered owing to the change in volume. The position of the mercury is then restored to the zero position by the micrometer. The reading of the micrometer is calibrated under known loads, and this calibration used in conjunction with the stabilizing box to check the testing machine.

The methods described above are applicable to most testing machines, but with single lever vertical machines a simple test can be carried out quickly and accurately in the following way:

As the load is weighed by a jockey weight, and as there is only one lever, it is only necessary to verify the weight of the jockey and the short arm-length of the lever to ensure that the machine is reading correctly.

(vi) Weight of the Moveable Counterpoise.—This can be found by lifting it from the lever with a suitable weighing machine suspended from a crane, or, where this is inconvenient, by means of the lever itself, in the following way. First balance the beam and adjust the

---

ELASTIC CONSTANTS

from the curve that the vertical distance between the two parallel branches is the local extension due to the necking of the test piece. In Fig. 48 the same results are plotted in another way. The increases in length in each inch are plotted as ordinates at the center of each inch length and connected by a curve. It is seen that the rate of elongation at the fracture is very large, and that the curve is nearly symmetrical.

From the figures in Table 1 the percentage elongations on various gauge lengths can be calculated. Taking the fracture as near to the center as possible, these results are given in Table 2 and are calculated as follows:

If the original gauge length \( L_0 \),

the final gauge length \( L_f \),

the elongation \( \Delta L = L_f - L_0 \),

and the per cent elongation \( \frac{100(L_f - L_0)}{L_0} \).
ELASTIC CONSTANTS

It will be evident from the table that the percentage elongation is dependent upon the gauge length, decreasing as the gauge length increases, and that for strictly comparative results the same gauge length should be adopted for bars of the same diameter. Also, for strict comparability, the position of the fracture should be the same in each bar. If the bar breaks near to the end of the gauge length the percentage elongation is low. The formula for calculating the error involved has been expressed by Unwin as follows:

"Let \( \epsilon_1 \) be the percentage elongation in a gauge length \( L + 2X \) and \( \epsilon_2 \) the elongation in a gauge length \( L - 2X \), the fracture being at the centre in both cases. Then the elongation in a gauge length \( L \) when the fracture is at \( X \) from the centre is \( \epsilon = \frac{1}{2}(\epsilon_1 + \epsilon_2)\)."

The results in Table 3, taken from Unwin's paper, show the magnitude of the error. Unless the gauge mark is in the part affected by the local contraction, the effect on the percentage elongation is small.

§ (16) Barba's Law (Elongation of Geometrically Similar Test Bars).—The law connecting the elongation of geometrically similar test pieces was first given by J. Barba in 1880, who observed that similar test bars deformed similarly. It follows that, for cylindrical specimens, if the ratio of gauge length to diameter is constant, the percentage elongation is also constant. This is shown clearly by the results on a mild steel and medium carbon steel given in Table 4.

Unwin says that "in plate test bars, not strictly geometrically similar, the percentage of elongation is practically constant, if the ratio of gauge length to square root of cross-section is constant. The form of cross-section within somewhat wide limits, if the area is constant, does not appear to influence the elongation." § (17) The Elongation Equation. (i) Variation with Gauge Length.—The elongation of a test bar is made up of two parts:

(a) The general extension, occurring before the maximum load is reached, which is approximately uniformly distributed along the bar and therefore proportional to the gauge length.

(b) A local extension independent of the gauge length occurring after the maximum load has been reached.

If \( L \) = the gauge length,

\[ \epsilon = \text{the total extension} \]
then \( \epsilon = a + bL \), where \( a \) and \( b \) are constants, the former for the local extension and the latter for the general extension. The percentage elongation

\[ \frac{\epsilon}{L} \times 100 = 100 \left( \frac{a + bL}{L} \right) = 100 \left( \frac{a}{L} + b \right) \]

For simplicity, let \( \sqrt{A} / L = a \), and suppose the elongations have been observed for a gauge length. Then the most probable values of the constants are given by the equations

\[ \frac{n\Sigma \epsilon - \Sigma \epsilon a}{\Sigma \epsilon^2 - \Sigma \epsilon^2 a^2} \text{ and } \frac{b}{\Sigma \epsilon^2 - \Sigma \epsilon^2 a^2} \]

Applying these results to bar 8d (Table 4), whose diameter = 1000 in. and area = 0.7854 sq. in., and percentage elongation on

\[ 3"' = 41.0, \ 6"' = 31.8 \]

we have

\[ 4"' = 36.5, \ 7"' = 30.1 \]

\[ \sqrt{A} = 0.8803 \]
and \( n = 6 \).

\[ \begin{array}{cccc}
L & \sqrt{A} & \epsilon & a^2 \\
3 & 2654 & 41.0 & 12.110 & 4.8723 \\
4 & 2216 & 36.5 & 8.088 & 0.6047 \\

</tbody>
</table>
The volume of the test piece is assumed to be constant, therefore

\[ l_1 \times a = l_2 \times A \]

or

\[ \frac{A}{a} = \frac{l_2}{l_1} \]

Subtracting each from unity, we have

\[ 1 - \frac{A}{a} = 1 - \frac{l_2}{l_1} \]

or

\[ a - A = l_1 - l_2 \]

The agreement between elongation and contraction of area is only for the short part of the specimen where there is plastic deformation, and it does not apply to greater lengths.

Professor Elliot \(^1\) has given a method of calculating the constants \(b\) and \(c\) of the elongation equation \(e = \sqrt{A/l} \times b\) when the elongation is only known on one gauge length together with the contraction of area of the test bar. The method depends upon the assumption of a value for the original length of the contracted region. Taking this as \(\sqrt{A/l}\), Elliot found that \(m\) varied from 0.9 to 2.0, and adopting the value of 1.37 he obtained very fair agreement with results previously published by Unwin.\(^2\)

### III. Procedure in Ordinary Commercial Testing

Commercial testing is undertaken primarily to ascertain if the material is of the quality required by a specification. These inspection or reception tests have to be made quickly, and are principally directed to giving indications of the strength and ductility of the material.

### § 19 Preparation and Selection of Test Pieces

The test pieces must be selected so as to give a reliable indication of the material as a whole. Sampling is inherently imperfect, and is therefore apt to cause difficulties. Samples should always be taken and stamped in the presence of an inspector acting on behalf of the purchaser, and there should be safeguards to avoid bent treatment or other manipulation after selection.

The number of tests should be specified, and, in order to cover errors which are likely to arise, limits should be allowed on the test results, and provision made for re-test if necessary. A usual clause is that, should the test pieces fail to conform to the specification, the contractor shall have the opportunity of two further samples being selected by the inspector and tested at the manufacturer's expense. Both of these samples must pass in order for the consignment to be accepted.

Test pieces, if to be taken from a sample, such as a tyte, axle, crank-shaft, etc., should be cut out by cold sawing or drilling, and subsequently prepared by milling, turning, or planing. Should shearing be unavoidable, care must be taken to ensure that the material is not bent, and that the sheared edges are entirely removed before testing. Cutting by masonry collet wheels should not be allowed, as it alters the structure of the material for from 2 to 3 in. from the cut.

Iron or steel plates are usually tested both in the direction of rolling and across it, and with cast iron special bars are made from each cast for transverse test. For some materials special bars form part of the casting and are afterwards cut off for testing, but it is usual to specify the position of these bars and whether they are to be sand or chill castings.

For special tests some form of heat treatment, such as normalising, annealing, or tempering, may be required.

Annealing means reheating to slow cooling. Its purpose may be either to remove internal stresses and induce softness, or to refine the crystalline structure. In the latter case the temperature used must exceed the upper critical range, but not more than by 50°C.

Normalising means heating a steel (however previously treated) to a temperature exceeding its upper critical range (but not more than by 50°C) and allowing it to cool freely in air. It is desirable that the steel should reach the required temperature for about 15 minutes.

Hardening means heating a steel to its normalising temperature and cooling more or less rapidly in a suitable medium, such as
ELASTIC CONSTANTS

water, air, or oil. Tempering is to reduce the hardness and increase the toughness, and is carried out by heating the steel (however previously hardened) to a temperature not exceeding its carbon change point.

§ (20) TENSION TESTS.—The data ordinarily observed in a tension test for reception purposes is

Yield load.
Maximum load.
Elongation after fracture.
Contraction of area at fracture.

§ (21) YIELD POINT AND ELASTIC LIMIT.—Very often there seems to be confusion as to exactly what is meant by the elastic limit and the yield point. It is a common practice for the elastic limit to be specified when what is actually required is the yield point. The actual elastic limit can only be obtained by the use of delicate strain-measuring instruments (see § (62)); the yield point is slightly higher than the elastic limit, and is the point at which there is an increase in the extension without a corresponding increase in the stress. This point occurs in wrought iron or mild or medium carbon steel, and is usually well marked. With hard steel, bronze, and most alloys it is non-existent, the rate of extension with load increasing after the elastic limit without any sudden jump.

For commercial testing the yield stress is the load per unit area at which there is a sudden visible increase in the extension between the gauge marks on the test piece, or it may be taken as the stress at which the beam or indicator distinctly drops when the load is applied at a uniform rate.

The author prefers to record that “there was no yield point” in cases where these conditions are not observed, but, as some specifications require an arbitrary yield point, it is taken at the point at which the test piece extends approximately 1/200 of the gauge length. With a 2-inch gauge length this, for practical purposes, is the point where the dividers, when set at 2 inches, just fail to “feel” the gauge mark.

Johnson 1 proposes that “in view of the difficulty of determining the true elastic limit an apparent elastic limit be taken as the point on the stress strain diagram at which the rate of deformation is 50 per cent greater than it is at the origin. Under this definition the apparent elastic limit would practically correspond to the yield point in materials having such a point and would give a reasonable value for such materials as cast iron, or hard steel, for which this diagram shows a very gradual curvature away from the straight line. Such a criterion has much merit and would accomplish the following results:

(i) It would always fix one and the same well-defined point.

(ii) This point would always correspond to so small a permanent deformation as to be, for many practical purposes, the true elastic limit.

(iii) It is equally applicable to all kinds of tests, whether on specimens or on finished members or structures, where deformations of any kind can be correctly measured.

While the 50 per cent increase in the rate of deformation is purely arbitrary, it is not large enough to fix a point having an appreciable permanent set, but it is large enough to fix a well-defined point on the stress strain diagram.”

Unwin, 2 however, says that “such a point has no significance,” also “that the attempt sometimes made to define arbitrarily a yield point for materials which have no distinct yield point, and, often as manufactured, no elastic limit either, appears to him to be useless and misleading.”

![Diagram](image)

It is convenient, where a considerable amount of testing has to be done on the same size of test piece, to use a simplified extension measure applied to the test piece instead of dividers. C. H. Roberts 3 describes and illustrates an instrument of this kind in which the extension of the test piece is communicated to the pointer on a dial. One division on the dial indicates a movement between the jaws of 0.001 inch. The yield point is seen quite definitely if it occurs, or the load for an extension of 1/200 of the gauge length can be also noted with fair accuracy.

Capp’s 4 multiplying dividers answer the same purpose. They are illustrated in Fig. 49, and consist of two arms so pivoted that the motion of the points in which the short arms terminate is multiplied about ten times at the scale and pointer forming the ends of the long arms. To use the instrument the points of the dividers are placed in the centre punch marks on the test piece and held firmly in place when the load is applied. The pointer moves across the scale slowly until the yield point, when a sudden and marked increase in the rate is observed.

§ (22) THE MAXIMUM LOAD.—An autographic

ELASTIC CONSTANTS

The stress-strain diagram shows that, with a test bar which "necks" before fracture, the actual load necessary to break the test piece at the neck is less than the maximum load on the bar before the necking of area takes place. Nevertheless, the stress obtained by dividing the breaking load by the reduced area is greater than the stress obtained by dividing the maximum load by the original area of the bar, which is the figure required by specifications.

The terms breaking stress, maximum stress, ultimate stress, and ultimate strength are applied indiscriminately to indicate the maximum load divided by the original area which is desired by specifications. It is obviously not the maximum stress, although it is calculated from the maximum load. As the term breaking stress is also liable to be misunderstood, the author prefers to call it the ultimate stress.

§ (22) PERCENTAGE ELONGATION AND CONTRACTION OF AREA.—In specifications the elongation and contraction of area are required in order to obtain a measure of the ductility of the material. Both are empirical values and the former, as has been shown in § (17), is dependent on the cross-section of the test bar and the gauge length. It has been suggested that the percentage general extension instead of the percentage total extension should be adopted, as this is independent of the form of test bar. It would, however, complicate the calculation of the results, and owing to the general adoption of the other method of expression would doubtless cause considerable confusion.

The general extension, if it is required, is obtained either

(I.) From an autographic diagram, as the extension at maximum load, i.e., before the necking of the test piece, or

(ii.) From the measurement of the elongation on two-gauge lengths on the same test piece.

Thus if \( \epsilon_1 \) = elongation on gauge length \( L_1 \),

\( \epsilon_2 \) = elongation on gauge length \( L_2 \),

\( \alpha \) = total local extension,

\( B \) = the general extension per unit length,

then \( \epsilon_1 = B \frac{1}{2} + \alpha \),

\( \epsilon_2 = B \frac{1}{2} + \alpha \),

and the general extension per unit length

\[ B = \frac{\epsilon_2 - \epsilon_1}{L_2 - L_1} \]

\[ \alpha = \frac{\epsilon_1 - \epsilon_2}{L_2 - L_1} \]

e.g. with a 30-tons steel, diameter = 1.000 inch,

Extension on \( 8^" \) = 2.37 inches (29.6 per cent).

Extension on \( 3^" \) = 1.32 inches (14.0 per cent).

\[ B = \frac{2.37 - 1.32}{8 - 3} = \frac{1.05}{5} = 0.21 \]

\[ \alpha = \frac{0.32 \times 8}{(2.37 \times 3)} = \frac{3.45}{5} = 0.69 \]

This is general extension \( B = 21 \) per cent.

§ (24) MEASURING THE EXTENSION.—The gauge length in ordinary commercial testing is marked on the bar before it is tested, by

means of either a double centro punch (Fig. 50) or a laying-off and per cent gauge (Fig. 51). It is, however, nearly as convenient and almost as quick to use a pair of dividers set to the correct gauge length. It is necessary to have a vee block to support the test piece during the marking-off process.

As long as the fracture is not less than a length equal to the square root of the area inside the gauge mark the measure of the elongation is usually accepted as satisfactory, i.e., 0.5 inch for a test piece of 0.25 sq. in., area or 0.7 inch for a test piece of 0.5 sq. in., area.

Sometimes it is specified that "should a tensile test piece break outside the middle half of its gauge length the test may, at the contractor's option, be discarded and another tensile test shall be made from the same bar, billet, sheet, forging or drop forging." The middle half is defined as shown in Fig. 52.

§ (25) METHOD OF RECORDING RESULTS.—It is desirable that the results should be reported in such a manner that the information can be assimilated as easily as possible. It adds greatly to the facility with which the results can be compared and scrutinized if the form of report is always in the same style. The following points are also worth consideration:

(1) The report should contain as far as possible the actual observations.

(2) The heads of information which are purely observational and those which have been reduced by calculation should be kept separate. It is convenient to have the latter on the right-hand side of the form.
ELASTIC CONSTANTS 14

A typical form for tensile tests is given in Fig. 53, together with the results of a few tests. It is seen that the information which the bar tested under tension, a concentration of stress is caused at the bottom of the groove or notch which is thus formed, while

It will be noted that, with the exception of the original area, the observed values are given in column 2 and the calculated figures in column 3. This method simplifies the typing of the report as given in Fig. 53.

§ (26) FORMS OF TENSILE TEST BARS.—It is shown by experiment that the form of the tensile test piece has an influence on both the elongation and the strength. The elongation with ordinary test bars is measured on a gauge length of uniform section. The effect of the enlarged ends is to reduce the local drawing-out of the material. The parallel part of the test piece is therefore always made somewhat greater than that on which the elongation is measured. If the length of the parallel section is reduced so as to form an abrupt change in cross-section of breaking load, while with a ductile material the suppression of the local drawing-out gives an increased tensile stress.

The influence of the gauge length on the percentage elongation has been discussed in § (17).

On account of the considerations stated above, it is essential that definite types of specimen should be specified for commercial tests, in which the results of the tests decide whether the material is to be accepted.

As a result of the work of Barlow, the French
Commission recommends the adoption of the relation
\[ L^2 = 0.647A \]
or \[ L = 7.29 \]
for circular specimens, where \( L \) = the gauge length, 
\( A \) = area of cross-section, 
\( D \) = diameter of the test bar.

The German Commission recommends the use of the relation
\[ L = 11.3\sqrt{A} \]
or \[ L = 100 \] for circular specimens.

Thus while, with a test piece 10 mm. diameter, a gauge length of 72 mm. is recommended in France, a length of 100 mm., is adopted in Germany.

Owing to the practical difficulties in the way of adopting a varying gauge length for different cross-sections of test piece cut from plates and other rolled sections, fixed standards for cylindrical and flat specimens have been

§ (27) **Enlarged Ends of Test Pieces.**

(1.) *Tensile Tests.* — The design of the enlarged ends of test pieces requires care in order to be sure of satisfactory results. It has already been stated that axial alignment of the test piece is necessary for accurate work and that this is best attained by the use of hemispherically seated holders.

For brittle materials it is essential that the transition from the parallel part of the test piece to the enlarged ends is gradual, and that any part of the enlarged ends which is screwed, or otherwise has a sharp corner, is sufficiently large to prevent fracture at that place. Forms of ends for turned test pieces of cast materials are given in Fig. 55.

Test pieces may be tapered inside the gauge length towards the centre, in an amount not exceeding 0.003 in. for turned test pieces and 0.01 in. for sheets or plates, in order to induce fracture near the centre of the gauge length. If this is done the middle half of the gauge length of the test piece should be parallel.

(2.) *Compression Tests on Metals.* — With the more plastic metals there is no well-defined point of break-down under compression, and it

For plates, both 10-inch and 8-inch gauge lengths were in use before the B.E.S.A. standard was published. A standard width of 2 inches was used for convenience in milling; this gave a cross-sectional area varying with different thicknesses of plate, and thus disregarded the effect of the cross-sectional area on the percentage elongation.

In order to overcome this difficulty the B.E.S.A. standardised test bars having a fixed gauge length of 8 in. and a width varying with the thickness of the plate. In order to lessen the cost of production, three widths only were chosen, viz.:

---

## Fig. 54.

prescribed by the American Society for Testing Materials (A.S.T.M.) and the British Engineering Standards Association (B.E.S.A.).

The sizes selected by the B.E.S.A. are given in Fig. 54. Those adopted for cylindrical test bars of forgings (Fig. 54) approximately satisfy the law of similarity, where

\[ L = 4\sqrt{A} \]

viz.:

---

## Fig. 55.

is usual to record the compressive strength at a given unit of deformation. The values which are obtained in this way are only
ELASTIC CONSTANTS

comparative and do not give results which can be used as a basis for calculating sizes of structures.

With brittle materials the ultimate stress can be obtained with precision, and the results are of value for calculating sizes of compression members.

For metals the test piece is usually a cylinder whose ratio of length to diameter is two.

It is important, especially with brittle materials, that a spherical seated shackle should be provided in order to adjust for inaccuracy of the parallelism of the shackles.

A form of shackle is shown in Fig. 39. Care should be exercised to ensure that the pressure is applied axially.

§ (28) QUALITY FACTOR.—Various empirical means of estimating the quality of the material from the results of the tensile test have been suggested. They combine the tensile strength with either the percentage of elongation or percentage contraction of area at fracture. The only factor which has been used to any large extent in this country is a modification of one suggested by Wahlert.

Wahlert's quality factor = \( p \times e \)

and the modified factor = \( p + e \),

where \( p \) = tensile strength,

\( e \) = per cent elongation,

\( c \) = per cent contraction of area.

A quality factor must be used with care, bearing in mind the use to which the material is to be put.

§ (29) BEND TESTS.—A rough workshop test of the ductility of metals is given by the bend tests of various types which are now in common use. The test is made by bending a piece of the material either by steady pressure or hammering, the former giving the more concordant results, until an angle of 180° is reached or previous rupture takes place. In the latter case the angle is noted at which fracture occurs on the outside of the bend. A large amount of experimental work has been carried out by Mr. Bernard Firth, but the test has not been so carefully standardized as the tensile test.

The test is also used for ascertaining the effect of punching and drilling on the ductility, by using perforated plate specimens with the hole in the centre of the plate. The diameter of the hole, as recommended by Murton, should be twice the thickness of the plate and the width of the specimen five times its thickness.

§ (30) KINDS OF BEND TEST.—The principal types of bend test in use are:

(i.) Cold bend test (as received).

(ii.) Cold bend test (annealed).

(iii.) Quench bend test or temper bend test.

(iv.) Hot bend test.

(v.) Nick bend test.

(i.) Cold Bend Test.—This is the type which is most commonly used and is carried out at normal temperature. To test the ductility at low temperature the test pieces are sometimes cooled artificially.

(ii.) Annealed Bend Test.—For the annealed bend test the material is, previously to bending, reheated to a temperature exceeding its upper critical range, followed by slow cooling. The steel is usually very bad if it cracks after annealing.

(iii) Quench bend test is used for determining the effect of alternations of high and low temperature on the ductility of such materials as boiler-rirot steel and stay-bolt iron. Before applying the bend test the material is heated to blood-red and plunged into water at a temperature of 80° F. The colour is judged indoors in the shade.

(iv.) The hot bending test is specified to detect red shortness or high sulphur content. The material is bent while at a temperature of about 050 to 1000° C.

(v.) The nicked bend test is intended to show whether the material has a crystalline or fibrous structure. The test piece is nicked all round, before bending, with a tool having a cutting angle of 60°. The depth of the nick is 8-16 per cent of the diameter of the test piece. The test piece should be placed so that the bend occurs with the minimum depth.

§ (31) FORMS OF SPECIMENS FOR BEND TESTS AND METHOD OF TESTING.—Rods are usually tested without machining. Plates should be placed at the sides after shearing, and the corners rounded with a file, otherwise cracks may start at the corners due to the shearing process having weakened the metal. With plates over one inch thick it is especially important that this precaution should be taken.

It is usual to bend bars, unless otherwise specified, round a mandrel of a radius equal to the diameter or thickness of the bar.

A cold bending apparatus is shown in Fig. 50, in which a steady pressure is applied during the test. The lower plate A rests on the table of the testing machine while the upper tool B is held in place in the pulling bend by
wing nuts and plate. The brackets CC are spaced sufficiently apart to allow the upper tool and twixt the thickness of the specimen to easily pass between the lower rollers DD. The rollers can be changed as to adapt the apparatus for either round, square, or twisted bars.

Where a large number of tests have to be carried out, and the testing machine or press cannot be spared, it is usual to have a special machine used exclusively for bend tests. A hand power machine for specimens up to one inch square is shown in Fig. 57.

The correct size of centre pin is first put in the machine, the crank arm is next rotated until the crank arm pin is below the level of the test piece, and then the table is adjusted by means of the small hand-wheel until the top of the specimen rests against the centre pin, which should lie at about the centre of the specimen. The graduated ring is set to zero, and power is applied to the crank arm, which revolves until the test piece ruptures or the required angle of bend, read off on the graduated ring, is reached.

A fatigue test is sometimes used as an alternative to the bend test. The test piece is placed on bearings with a span of 6 in., and must stand without fracture twenty blows from a weight of 1120 lbs. having a rounded end of 1 1/2 in. radius and falling 6 in. The test piece is to be reversed after the first and very alternate blow. The height of fall after twenty blows is increased to 13 in. and the test continued until fracture occurs.

Bend tests are now often replaced by single blow notch bar tests (see § (88) to § (101)); but these require special testing plants.

§ (32) Tests for Rivets.—Rivets are usually subjected to a bend test and a flattening test. For the bend test they are hammered cold without cracking until the two parts of the shank touch (Fig. 58 (A)) and for the flattening test the heads are hammered while the rivet is hot and must flatten without cracking of the edge to a diameter 2 1/4 times that of the shank (Fig. 58 (B)).

§ (33) Bending, Drifting, Flanging, and Flattening Tests for Copper and Brass Tubes.—It is usually specified that brass and copper tubes shall stand a certain percentage increase in the diameter (25 per cent is usual) without cracking or blow when subjected to bending (Fig. 59 (A)), drifting (Fig. 59 (B)), or flanging (Fig. 59 (C)). Another test which is frequently imposed is flattening and doubling over. It is generally carried out both cold and at red heat. The tube is flattened and doubled over through 180° as shown at Fig. 59 (D).

§ (34) Drift Test of Metals.—Another workshop test for ductility, which is applied with ordinary shop appliances, is to bore holes
drift (taper 1 in 10) until cracking occurs or a definite increase in diameter is reached. The hole is usually 3 inch diameter and 1½ inch from the edge of the plate.

The following table gives comparative figures for various sizes of plate:

$\Sigma (35)$ FallinG WERT TEST (called "drop test" in U.S.A.)—The falling weight test is considered to be a most useful test for rails and is given a prominent place in rail specifications. It is made by placing a piece of the rail 4 ft. long on supports 3 ft. apart and dropping a heavy hammer, through varying distances, on to it at the mid-point of the full, radius of striking face, and supports, and form of foundation must be specified. There is a difference of opinion however on this point, more especially in regard to the foundation of the machine.

Particulars of the standard machines usually adopted in the United States of America and in Great Britain are given in Table 6.

The atmospheric temperature is usually reported, and due allowance is made for rails tested at or below 0° C.

The falling weight test is also applied to tyres and axles. For tyres a weight of 2240 lbs. is allowed to fall freely from 10, 15, 20 ft., and upwards on the tread; the tyre being placed in its running position upon a heavy cast-iron anvil supported by a rigid concrete foundation. The tyre must deflect a given amount without fracture.

If $d =$ internal diameter of tyre, as rolled, in inches,
$t =$ thickness of the centre of the tread, in inches,
$d]=$ diameter of the roll, in inches,
deflection $= \frac{d-2t}{d}$,
where $c$ is a constant depending on the breaking stress of the material (see Table 7).

§ (37) Testing Cast Iron. (1) Transverse Test.—Owing to the ease with which it can be carried out, the transverse, or cross-breaking test, has been universally adopted as the standard for cast iron. The test is carried out by breaking the test-bar as a beam loaded centrally. The strength is measured by the central load with which the bar will carry. When, in order to obtain comparative results, the modulus of rupture is used, it is necessary to obtain the tensile strength of the material. The modulus of rupture is found from the formula

\[
\frac{W L}{d^2} = f \times z, \quad \text{or} \quad f = \frac{W L}{d^2} \times \frac{1}{z}
\]

Above the elastic limit the stress calculated from the formula varies for the same material with the form of the section, but if the breaking load \( W_b \) is substituted for \( W \), a value of \( f \) is obtained which is a measure of the quality of the material for bars of similar section, and is called the modulus of rupture.

C. Hailston, in 1914, as a result of a series of experiments on cast iron when tested by cross-breaking, finds that whereas the ratio of the breaking loads for 1 \( \times 2 \times 1^2 \) (span) and 1 \( \times 1 \times 1 \) (span) beams is 1:33:3 if the formula \( W L \times d^2 = f z \) is taken as applying up to the point of rupture, the actual value is 1:13:3 if the pieces are machined, and 1:16:1 when tested with the skin left on. He further finds that the best test-bar to give the most consistent and comparable results is 2 \( \times 1 \) \( \frac{1}{2} \) \( \times 2^2 \) cast on the flat and machined down to 2 \( \times 1 \) and tested.

\footnotetext[2]{Iron and Steel Inst. Journ., 1914.}
ELASTIC CONSTANTS

The results in Table 10 of tests on grey cast iron by Mathews show that the modulus of rupture decreases as the span increases; the cross-section being circular (14 in. diam.) and kept constant.

Table 11, compiled from figures recorded by J. E. Stead, gives a comparison of results obtained on British, American, and German standard bars. His conclusion is that it is desirable that any bar for testing for deflection by transverse stress should not be less than 24 in. long, as, with shorter bars than this, it is very difficult to measure the required degree of accuracy except with very delicate measuring instruments.

In commercial work a deflectionometer of the type shown in Fig. 60 is generally used. It consists of a cast-iron base the bottom of which is carefully planed. This base carries a scale along which a lever moves a vernier reading to .001 in. The adjusting screw of the lever is arranged under the transverse tool so as not to be affected by the breaking of the specimen. A simple arrangement which is sometimes adopted is to use a Brown and Sharp lathe indicator under the transverse tool at the centre of the beam.

---

(1) Square bars, in general, exhibit a slightly higher modulus of rupture than round bars of equal area. Tests by a committee of the American Society of Mechanical Engineers give an average of about 5 per cent higher.

(2) Bars cast horizontally are strongest when the load is applied against the edge face.

(3) Rough bars are stronger than planed bars.

(4) Tumbling in a rattler increases the hardness of the skin and therefore improves the strength.

(5) Bars run with hot metal are weaker and deflect more than bars run with dull metal.

(6) Tapping a bar with a hammer during test reduces its strength.

(7) For bars of the same proportions, the modulus of rupture is lower as the section is larger.

(8) A wide bar gives a higher, and a deep bar a lower modulus of rupture.

With the English standard test pieces

---

Elastic Constants

(1" wide, 2" deep, 42" long, and 36" span) the strength of cast iron is usually specified by its breaking load in cwt., figures of 18, 28, and 38 (cwt.) corresponding to poor, fair, and good cast iron. A usual specification is that the cast iron shall sustain a load of 30 tons, not with the centre of load at a distance of not less than 3 in.

A form of report which is suitable for transverse tests is given in Fig. 61. It enables the salient points of the results to be seen at a glance, and meets all ordinary cases on the testing of cast iron.

(ii.) Effect of temperature on the transverse strength of cast iron.—Cast iron loses very little of its strength or toughness up to a temperature of 400°C. The following sets of experimental results by Moyer show this very clearly.

Table 12  
EFFECT OF TEMPERATURE ON THE STRENGTH OF CAST IRON

§ (38) Tensile strength of cast iron.—It is important when making tensile tests on cast iron to ensure that the pull is axial in this material is greatly weakened by oblique or eccentric loading. For accurate testing, shackles with spherical seats should be employed (see Figs. 33 and 34), the test bar should be cast in one with the work and turned to a suitable size, care being taken to avoid rapid changes of section near the part of the specimen under test.

The size of the bar from which the test piece is taken affects the results obtained, bars of larger section giving, as a rule, lower results.

Tables 13 and 14 give results recorded by J. B. Stead on test pieces prepared from bars of various sizes which have been cast in different ways.

Table 10 gives results obtained by Mathy on cast iron containing various percentages of silicon.

A comparison between the modulus of rupture and the tensile strength is given in Table 15.

§ (39) Crushing strength of cast iron.—The crushing strength of cast iron is obtained on cylinders or prisms in which the ratio of the height to the least lateral dimension is between one and three.

The crushing strength is usually about five times the ultimate tensile stress, and samples of bad, good, and very good cast iron should give a crushing stress of 30, 40, and 50 tons per square inch respectively.

§ (40) Resistance of cast iron to direct shear and torsional shear.—As the result of experiments in direct shear by Platt and Hayward it was thought that the shearing strength of cast iron was about five to six tons per square inch. Izod, however, by using...
ELASTIC CONSTANTS

more perfect apparatus, has obtained much higher figures, and these are confirmed by Goodman. The results of these tests, together with the figures obtained from gun-metal and giving a lower result in shear than in tension.

Fremont is of opinion that the shear test gives a very useful indication of the quality

</table>

Only test pieces which broke with a sound fracture are included in Tables 13 and 14.

The point of interest in Table 16 is the fact that the shearing strength of cast iron is higher than the ultimate tensile strength. Goodman says that, with the exception of specimens which are defective on account of blowholes or sponginess, he has never had a single instance of a specimen of cast iron of cast iron if the sample tested truly represents the material of the casting. He has devised a special test for this purpose.1 A small piece of the actual casting, 23 mm. diameters and 20 mm. long, is detached by a trepanning tool. The specimen is placed within a block holding a fixed blade, and is cut by a movable blade which is forced into the specimen by a weight

1 Fremont, Complete Reader, Dec. 6, 1918.
ELASTIC CONSTANTS
acting on a lever. The force of rupture is estimated from the weight and leverage. Since
the diameter of the hole bored in the casting is only about 14 in. diameter the casting is
not spoiled by this method of procedure.
Under torsional shear a small bar of cast
iron invariably fractures along a helix whose
angle is 45°, that is to say, it occurs where the
tensile stress is a maximum, and indicates
that cast iron has a lower resistance to tension
than to shearing. This conclusion confirms
the direct shear results of Izod and Goodman.
A typical torsion fracture is shown in Fig. 02.
§ (41) INFLUENCE OF FORM ON THE PROPERTIES OF MATERIALS.—An abrupt change in
the cross-section of a tensile or transverse test
bar causes:
(a) A diminution of the elongation at the
reduced section due to the shoulders of the
notch or groove.
(b) The stress to be highly concentrated at
the periphery of the groove or notch.
There are thus two effects—the suppression
of the drawing out of the material causes a
gain of strength, while the inequality of the
stress on the section of fracture gives a re-
duction in strength.
With a brittle material, e.g. cast iron, the
elongation is negligible, and in consequence
the effect of a groove is to cause a reduction
of strength. On the contrary, a grooved mild
steel test piece is stronger than a plain bar of
the same material, because the suppression
of the drawing out causes an increase in strength
which is greater than the effect due to con-
centration of stress at the groove acting in
the opposite direction.

(6) The Effect of Perforation on the Strength of Mild Steel Plates.—In the afternoon
a paper by W. Hackney before the Insti-
tute of Civil Engineers, Straneley 1 described
experiments carried out to determine the e
f of perforation on the tensile strength
elongation of boiler plates. The forms of
bars that he used are given in Fig. 03, and
results are given in Table 17.

The test pieces are all cut from one plate 12 mm. (f) thick, and the holes

all 24 mm. (d) diameter. The width (b) was
in different bars from 7-6 to 54-0 mm.
(ii.) Strength of Screwed Bolts.—The result
of some tensile tests on four different kinds

screw threads, made by the author, are given
in Table 18. The threads selected were:

the results in Table 18 it is seen that for steel up to 40 tons per square inch the

strength (per square inch of section taken at the bottom of the thread) is greater for the
bolts than for the plain bar, but that for the 03-ton steel the bolts, with the exception of

and 23.9 tons per square inch respectively.

His conclusions are as follows:

(1) Screw threads subjected to plain tension

1 Zeits. Vereines Deutsch. Ing., April 27, 1890.
are stronger than plain bars of the same net cross-sectional area, the excess of strength being approximately 14 per cent.

(2) There is no marked difference in the ultimate strength with different forms of threads—the sharp thread is slightly stronger than the others.

(3) Under repeated loads and impact it is probable that the sharp vee threads would develop cracks quicker than the other forms, and that the Whitworth thread would be the last to show this weakness, either with repeated loads using soft material or static loads with high carbon steel.

The two sets of experiments, by different experimenters, described above are in agreement. It will be seen that Marten's supposition with regard to the superiority of the B.S.W. thread with high carbon steels under static loads is shown by the author's tests to be correct.

With regard to Marten's statement of the probable weakness of sharp vee threads under impact, some tests by the author also confirm this conclusion. The tests, of which the results are given in Table 19, were made on 1-lb. bolts and broken by a single blow, the energy absorbed in fracture being measured. It will be noted from the table that the sharp vee bolts are the weakest of those tested and the British standard threads the strongest.

§(42) Influence of Time on Test Results.

General experience shows that elongation and contraction of area are increased by very rapid loading, but that within the ordinary limits of time occupied by a tensile test to fracture, of most materials, the rate of loading does not appear to have any effect on these results. The results from various experimenters, however, are not quite consistent.

(2) Effect of very Rapid Loading.—Maitland 1 found that steel, broken in impact, gave 74 per cent more elongation than the same material broken in the static tensile testing machine. Blount, Kirkaldy, and Sankey 2 concluded that the impact tensile test gave the ductility

ELASTIC CONSTANTS

the effect of time on the breaking load of soft iron wire. He found that the wire, if loaded to just below the ordinary breaking load, increased in strength according to the time the wire was under this initial load.

A summary of the results are given in Table 20.

IV. MEASURING INSTRUMENTS FOR THE DETERMINATION OF THE ELASTIC CONSTANTS OF METALS

In order to obtain information as to the elastic constants of materials it is necessary to measure deformations while these materials are being strained elastically.

In commercial testing, where a measure of the ductility only is required, the final amount of deformation is all that is necessary. In a tensile test with a standard 2-in. gauge length and cross-sectional area of 0.05 sq. in., the total elongation may be 0.50 in., and so this can be measured by the aid of dividers to the nearest $\frac{1}{10}$ in. the accuracy of reading is 2 per cent.

Using the same size of test piece and gauge length, the extension at the elastic limit is of the order of 0.002 in., so that for the same percentage accuracy the measurement must be correct to 0.00001 in.; the smallness of this extension can be realised when it is considered that the thickness of a piece of cigarette paper is about 0.001 in. With the best types of mirror extensometer, alterations of length can be accurately measured to $\frac{1}{10}$ of this amount, i.e., 0.000001 in.

§ (13) EXTENSOMETERS.—In any type of strain-measuring apparatus there are certain general principles which it is advisable should be fulfilled.

(i.) If changes in length of the axis of the test bar are to be determined, the apparatus should be taken on opposite sides of the specimen. Unwin has shown that, if this condition is not satisfied, initial curvature of the bar will cause serious errors in the results, but if the mean of measurements taken at points symmetrically placed on either side of the bar is adopted, the error due to curvature is nearly eliminated, the lengthening of the distance on one side being compensated by shortening of the other.

(ii.) The apparatus should be directly attached to the test piece at the gauge points only, and after the initial setting it should not be necessary to handle it during the course of the experiment.

(iii.) The instrument should be as light as possible, and designed so as to be rapidly attached to or detached from the test piece without interfering with the application of the load. It is advisable that, if possible, it should be self-contained.

(iv.) The instrument should be arranged so that its accuracy can be determined by a calibrating device, and the attachment to the test piece should be such that the gauge length is capable of determination with sufficient accuracy.

(v.) The mechanical or optical details, and the relative positions of all the parts with respect to the axis of the specimen, should be such that the "constant" of the instrument is the same throughout its range, or that any errors which are involved are so small as to be of no importance.

(vi.) The zero of the instrument should be constant for the same conditions of test; thus if, after straining the test piece, there is no permanent set the instrument should return to its initial position.

Extensions are measured in five different ways:

(i.) With a micrometer screw.

(ii.) By an indicating dial.

(iii.) With a microscope.

(iv.) By a multiplying lever (mechanical magnification).

(v.) By optical magnification.

With methods (i.), (ii.), and (iii.) the deformations are ascertained with little or no magnification, while with instruments employing methods (iv.) and (v.) the strains are considerably magnified before the measurements are made. Some extensometers use a combination of (iv.) or (v.) with (i.), (ii.), or (iii.).

§ (14) MICROMETER SCREW EXTENSOMETER.

—These instruments consist of two clamps placed on the test bar at a distance apart which is equal to the gauge length. The movement of one clamp relatively to the other, as the load is applied, is measured by the reading of one or more micrometer screws fixed to one clamp and brought into contact with the other. The accuracy of the instrument depends on:

(a) The uniformity of the pitch of the micrometer screw.

(b) The constancy of the pressure at the point of contact.

(c) The care with which the micrometer screw is operated, because the instrument has to be touched by hand many times during the experiment. Care should be observed in order to ensure that the couple applied by the fingers is perpendicular to the axis of the screw.

Micrometer screw extensometers are largely used in the U.S.A. by students, and give satisfactory results when used with great care. The principal makers of instrument are divided into two sections according as to whether they have one or two micrometer.
§ (45) Double Micrometer Screw Instruments. (i.) Professor H. B. Marshall’s Extensometer (1873).—This was the first instrument in which two micrometer screws were used, one placed on each side of the axis of the test piece, and in which electric contact was employed in order to eliminate errors due to variation of pressure.

(ii.) Henning’s Micrometer Extensometer.—This instrument is shown in Fig. 64. Two frames A and B grip the test piece by two steel points h, k and two knife edges c, c. The lower frame B carries two micrometers m, m, and the upper frame A provided with a pair of plugs, g which are in line with the micrometers. As the distance between the frames increases with application of the load, the ends of the screws f, f are brought in contact with the plugs g, g. The contact is initiated by ringing an electric bell by a weak electric current, or owing to the uncertainty of bell mechanisms, telephone receivers are sometimes substituted. The extension is read on vertical scales e, e and the graduations of the micrometer heads m, m.

The instrument registers to one ten-thousandth part of an inch, and can be used on either round, flat, or square specimens. In order to attach the extensometer to the test piece, the frames A and B are opened. Bars d are used for setting the frames A and B at the correct distance apart; they are removed while the test is in progress. An instrument of this type is supplied by Messrs. Thos. Olson Testing Machine Co., Philadelphia, under the name of the Olson Standard Duplex Micrometer extensometer.

(iii.) The extensometer invented by C. A. Marshall, of the Cambria Iron Company, differs from Henning’s in three small details. The adjusting bars d (Fig. 64) are omitted and the knife edges c, c are replaced by a spring and roller attachment which, in connection with a spirit level, assists in the accuracy of the adjustment. The micrometer screws are placed nearer the lower frame than in the Henning extensometer.

(iv.) The Yule extensometer is a simplification of the Marshall apparatus. The spring rollers are omitted and a gauge bar introduced to keep the clamps parallel, bringing the points of measurement opposite, and extending the length. The gauge bars are made of different lengths and are removed before beginning to strain the specimen. It reads to ten-thousandths of an inch by micrometer screw.

§ (46) Single Micrometer Screw Instrument. Unwin’s Screw Extensometer.—This instrument is shown diagrammatically in Fig. 65. The two frames are clamped to the test piece at points on a plane passing through its axis by set screws a and b. The lower frame carries the micrometer screw c, on the hardened point of which the upper frame rests. Provided that the frames are at right angles to the axis, the micrometer screw gives the variation in the length between the two points of support on the test piece. To set the frames normal to the axis of the test bar, levels e, f are attached to them. Level c on the lower frame is adjusted by the screw d, while the upper frame is set level by means of the micrometer screw e. The pressure on the micrometer screw is thus constant, and equal to the weight of the upper frame.

§ (47) Single Micrometer Screw Combined with a Multiplying Lever. (i.) Garrett’s Extensometer.—In this instrument (shown diagrammatically in Fig. 66) there is a mechanical magnification of two, combined with measurement by means of a single micrometer screw. Two pairs of steel plates B and C are attached to the test piece by screws E, E and pivoted together at F. The micrometer M is pivoted to the lower plates and carries a spindle H which passes through a guide K pivoted to the upper plates. The spindle carries a hardened pin on its upper end, and when the test piece extends, this pin, which forms part of an amnom barometer, moves the amnom needle. Half of the amount which

---

---

---
the micrometer has to be moved to bring the needle to its original position is a measure of
the extension.

reads the average stretch from two sides of the test bar with one micrometer screw. The
arrangement is shown diagrammatically in Fig. 07. The two frames A and B are
each fixed axially to the test piece by two hardened steel pointed thumb screws S, S.
The left-hand rod R is rigidly joined to the lower frame B and is pivoted in the upper
one A. The right-hand rod swings from a pivot in the upper frame over the micrometer
screw in the lower one. The rods are equidistant from the points of attachment to the
specimen, so that when elongation occurs the right-hand swinging rod moves away from
the micrometer twice the amount of the elongation. This extensometer can be used on gauge
lengths from 2 in. upwards by having sets of

![Fig. 07.](image)

rods for these gauge lengths which are required. Elongations of 0-0001 in. can be easily read,
and electric contacts can be employed with the instrument.

(iii.) The Cambridge Extensometer (Fig. 08).

- This simple and accurate extensometer is
made by the Cambridge and Paul Instrument
Co. Ltd., Cambridge, and is especially designed
for use as a workshop instrument. It is com-
posed of two separate frames, each of which is
attached to the test bar M by hard steel conical
points PP and PP' arranged in geometric
slides so that, after the points are gently
driven into the punch marks, they can be
champed in position by the knurled heads R, R. The lower frame carries a micromo-
ter screw H and a vertical arm B at the
top of which is a hardened steel knife
eedge about which the two frames work
together. The micrometer screw is pro-
vided with a hardened steel point X over
which a nickel-plated flexible steel tongue
A, forming a continuation of the upper
frame, is carried. The tongue and frame
form a lever magnifying the extensions of
the test piece by five.

In use the vibration of the flexible
tongue takes the place of the electric
contact, in the instrument previously
described, as a delicate means of setting
the micrometer screw. The steel tongue is
vibrated and the screw turned until the
point X just touches the hardened knife
eedge of the tongue as it vibrates. Read-
ings can be repeated by this means to
0-001 mm. under ordinary conditions of
test. The standard instrument is suitable
for specimens up to 1 in. diameter on a
gauge length of 4 or 2 in.

§ (48) INSIGNING DIAL INSTRUMENTS—
This type of instrument consists of one or
more calibrated dials with pointers on nicely
mounted spindles. These take the place of
the micrometer screws in the previous class
of extensometers, and are self-indicating
for large or small deformations. They are
generally used in conjunction with some
form of lever magnification.

Messrs. T. Olsen supply a dial extensome-
ter of exactly the same form as Hounston's
extensometer (§ 45) except that dials and
sliding rods replace the micrometer screws.
The sliding rods are attached to the lever
frame in place of the micrometer screws, and
spindles, carrying drums and pointers, are
fixed to the upper frame with their axes
horizontal. These take the place of the plugs
A, B (Fig. 45). The friction of the sliding rods
against the small drums (1 in. circumference)
causes the latter to rotate. This also rotates
the spindles and pointers round calibrated
discs.

§40 DIAL EXTENSOMETERS WITH MECHANICAL
MAGNIFICATION. (i.) University of Wis-
consin Wirewound Extensometer.—This
has one dial attached to the upper frame which
is operated by a wire arranged to transmit
twice the extension of the test piece to the
dial drum.

(ii.) Hurst-Toulmin Extensometer (Com-
bined Lever and Dial), Fig. 50.—This instru-
ment has been especially designed for use on
the standard test piece (0·004 in. diameter and
2 in. gauge length); it can be used, however, on
specimens up to one inch in diameter. The
gauge length of 2 in. is not adjustable, but the
instrument can be attached to specimens of
greater length than this if required. It is
provided with two forked levers, A and B,
fixed at the fork with pointed clamping screws which, when tightened on to the test
piece, form the pivots of the levers.

The dial indicator C is attached to one end
of the upper lever, and the other end, beyond
the test piece, has a stout vertical lug D ex-
tending downwards from one extremity of the
fork nearly to the level of the lower lever. Here
the lug bends inwards, and one arm E of the
fork of the lower lever extends inwards
in the same way.

The two levers are connected by a short
length of piano wire which ties in the central
vertical plane of the two levers.

This forms an elastic hinge, so that as the
test piece stretches the free ends of the levers
open away from one another.

This method of connecting the levers also
permits the test piece to be straightened out
slightly under the load, if originally slightly
bent, without straining the extensometer.

The lower lever is shorter than the upper one,
and it carries at the free end a short vertical
screw F with a large milled head.

The end of the screw is rounded and polished,
and bears on the end of the shorter arm of a
third lever G which is attached by a short
length of flexible steel ribbon to a bracket
which is screwed and dovetailed to the upper
main lever.

The end of the longer arm of this third lever
bears upwards on the end of the plunger of the
dial indicator.

The system of levers is proportioned so that
the movement transmitted to the indicator is
ten times the extension of the test piece.

By turning the milled head of the screw F
the dial indicator can be brought to zero before
the load is applied; a light spring maintains
the end of the small lever in contact with the
point of the screw. While the extensometer is
being attached it is necessary for the two main
levers to be rigidly locked, with the axis of the
clamping points parallel and at a distance of
2 in. apart.

This is accomplished by inserting two
locking pins, one of which constrains the axes
to be parallel while the other fixes the distance
between them.

The first pin is placed in the same horizontal
plane as the wire hinge, and its axis intercepts
the centre of the wire so that the insertion of
this pin leaves the levers only one degree of
freedom.

The second pin currently fixes the relative
positions of the two levers.

In order to ensure that the clamping points
shall grip the test piece along a diameter and
not along a shorter chord, two screws are
placed in the forked part of each lever inclined
at about 45°.

The axis of these screws intercept the axis
of the test piece and the ends are rounded to
bear at points on the test piece.

The usual diameter of the reduced part of
the test piece is 0·004 in., which gives a tran-
sectional area of 0·25 sq. in., and the length of
the screws is such that when just tight the
ends are 0·282 in. away from the vertical
plane through the clamping points.

When attaching the extensometer it is
simply held up against the test piece bearing
on the ends of the four screws, and the clamping
screws are tightened and the points placed the
test piece along two diameters. The extensim-
Elastic Constants

The determination of elongations by this method is a lengthy process, and except for special purposes it has been abandoned.

*Fig. 70* shows an arrangement of two microscopes which is convenient for measuring the extensions of strained cables. Microscope A has ordinary cross wires while microscope B is fitted with a micrometer eyepiece. Both microscopes are attached to a bar C which can be moved vertically by the screw D. Both microscopes are focused on scratches on the test piece and the load applied. By means of the screw D the cross wire of the top microscope A is made to coincide again with the top scratch, while the adjustable cross wire is moved in the second microscope to the new position of the bottom scratch. The movement of this cross wire in the calibrated micrometer eyepiece gives the extension.

§ (51) Combined Microscope and Lever Extensometer, Rising Extensometer.—This instrument has been used for a great deal of the scientific work in this country. It is shown diagrammatically in *Fig. 71*, and in its latest form in *Fig. 72*. The two clips, B and C, are each attached to the test piece A by two pointed screws. Clip B carries the vertical projection B' (*Fig. 71*) terminating in a milled point P which engages with a conical hole in C. The pieces B and B' are joined to one another in such a way that the test piece may twist a little without affecting the engagement of P with C. When the test piece extends, P serves as a fulcrum for the clip C and point Q is displaced through a distance equal to twice the extension. This displacement is measured by a microscope attached to B, sighting on a mark on the rod R hanging from the point Q on the upper clip. The readings are taken from a micrometer scale in the eyepiece of

---

the microscope. The screw (1, Fig. 72) serves to bring the sighted mark to a convenient point on the micrometer scale and also determines the scale readings which can be estimated to 0.0002 in. A clamping bar is added by which the clamps B and C are held at the correct distance when fixing them on the test piece. This extensometer is made by Messrs. The Cambridge & Paul Instrument Company for gauge lengths of 2 and 8 in. and 10 and 20 centimeters.

An apparatus for marking off the gauge points (Fig. 72A) is supplied with the instrument.

§ (52) OPTICAL MAGNIFYING EXTENSOMETERS.

(i) Kennedy's 1 designed a simple lever (leverage 100 to 1) extensometer clipped to the test bar at two points.

Martens's 2 lever extensometer is a modification of the Kennedy instrument, and is arranged to take simultaneous readings on two opposite sides of the specimen. It is shown diagrammatically in Fig. 73, and consists of two clamps D, D carrying the graduated scales C, C, and held on opposite sides of the specimen by a spring S. Diamond-shaped pieces A, A, to which the arms B, B are attached, are pivoted in shallow seats formed in the clamps D, D. With a magnification of 50, readings can easily be made to 0.002 mm.

(ii) Kennedy's 3 horizontal extensometer is gripped on the bar at four points in an axial plane and consists of two frames, one fixed to each gauge mark, which rest on each other over the points of attachment to the test bar. A light pointer is provided with two steel points, one resting on such frame. When the test bar elongates the two points move relatively to each other in an axial direction, and this movement is magnified by the end of the pointer which travels over a scale carried by a rod attached to one of the frames.

Other instruments of this type have been designed by Strainiuyer, 4 Goodman, 5 Wickham, 6 Ashcroft, 7 Col. W. H. Patins, 8 and Dunlop. 9

§ (53) OPTICAL MAGNIFYING EXTENSOMETERS.

—scale greater accuracy than 0.0002 in. in measuring deformations some form of optical lever is generally employed in which the change of length of the test piece is converted into rotary motion of a mirror which is observed by means of a telescope and scale. Some extensometers employ two mirrors in which readings are obtained from opposite sides of the test bar, while in others the main extension is measured by the reading from a single mirror.

(i) Two Mirror Apparatus. Bausch & Lomb's Instrument. 10 The introduction of mirror extensometers is principally due to Bausch & Lomb, who designed the instrument shown in Fig. 74.

Fig. 72A.

Fig. 72B.
Two clips, \(a, a\) and \(b, b\), are pressed against the specimen; \(c, c\) are light springs which press outwards against the rollers \(d, d\). These rollers, which are of camphene, are carried by the clip \(b, b\), and themselves carry the mirrors \(g, g\). As the specimen extends the rollers rotate, and these rotations are measured by means of the telescopes \(E, E\) and scales \(f, f\). The results are recorded to 0.0001 mm.

(ii.) Martens's Mirror Extensometer.—This is an improvement of Bauschinger's instrument and is shown in Fig. 75. It is extremely accurate and sensitive and is most adaptable. In this arrangement the multiplying levers of Martens's lever extensometer (Fig. 73) are replaced by small mirrors \((m, m, Fig. 75)\) which are attached to the rhombic-shaped pieces of steel acting as fulcrums, in such a way that the reflecting surface of each mirror is on the axis of the fulcrum. The two clips \(d, d\) are held on opposite sides of the specimen by a spring \(s\) which rests in grooves \(c, c\). Each clip is pointed at one end which is gripped directly on the test bar, while the other end has the rhombic piece interposed between it and the bar. The mirror is mounted in a frame by means of pivots centred in small holes drilled in the glass. In order to adjust the position of the mirror the frame is free to revolve on the axis of the rhomb. An adjusting screw \(b\) and spring \(p\) are placed on opposite sides of the mirror to control its

![Diagram](image-url)
position about an axis at right angles to that of the rhomb.

A pointer Q is attached to the rhomb and arranged so that, when it coincides with a mark on the clip d, the instrument is set at the proper gauge length.

Extension of the test piece rotates the rhomb, and the angular rotation is measured by a scale and telescopes as described for Bunsen's extensometer. Two readings are necessary, one for each rhomb, and two telescopes are usually employed.

At the X.P.L. a "one telescope" arrangement has been in use for some years with complete success. This is shown diagrammatically in Fig. 76.

The telescope T is attached to a support P, immediately under the telescope, and attached to the same support, is a platform S. The platform P whose height from the ground can be quickly adjusted. It can be looked in any position by a knurled-headed screw A. The telescope arrangement is kept in contact with the platform by means of a spring B, and their relative position in a horizontal plane can be accurately adjusted by means of the pivot rod and screw C.

The platform carries an illuminated scale D, two fixed mirrors M₁ and M₂, and two mirrors N₁ and N₂, pivoted vertically so that their position can be altered by means of the screw and spring E.

The illuminated scale is reflected from one of the "Martens" twisting mirrors on to the pivoted mirror N₁, and the angle of this is adjusted to bring the reflection into the telescope by means of the fixed mirror M₁. The other "Martens" mirror is made to reflect the illuminated scale on to the pivoted mirror N₂, and this is adjusted to bring the reflection into the same telescope. The difference between the lengths of the two rays is so small that the telescope can, at the same time, focus the scales reflected by each of the Martens rotating mirrors. The mirrors reflect "ghosts," and these are cut out by inserting a mask (Fig. 77) in the eyepiece of the telescope, and by having adjustable brass shutters (R, Fig. 76) fixed in between the mirrors on the platform and the extensometer.

The mirrors used must be absolutely flat, and great care should be taken to see that they are not distorted when they are clamped in position.

A curved scale should be used, but readings can be taken on a straight scale and a correction applied. The illuminated scale is graduated in millimetres and readings of the scale can be estimated to 0.1 mm.

If \( l \) is the width of the rhombs, \( l = \text{distance from the scale to the axis of the test piece}, \)

\[ x = \text{extension of the test piece}, \]

\[ X = \text{mm of the readings from the two Martens mirrors}. \]

\[ \frac{x}{X} = 0.144l \]

Usual values of \( l \) and \( L \) are 0.180 in. and 45-0 in, respectively. If \( X \) is measured in millimetres we have

\[ x = \frac{1}{4}X \]

\[ \frac{4}{4} \times 0.18 \times 45 \times 4 = 0.001 \times X \text{ millimetres.} \]

By providing suitable clips this extensa-
It is shown diagrammatically in Fig. 79. The attachment to the test piece \( T \) is by four set screws \( AA \) and \( BB \). \( AA \) serves as a fixture for the top annular ring \( C \), and when the test piece extends, the movement between \( C \) and \( P \) (which is an extension of the bottom ring \( D \)) is approximately twice the extension. So far the principle is the same as that of the Ewing extensometer, but whereas Ewing measures this extension by a micrometer microscope, Morrow uses a "Marten's" clump \( H \) to which a mirror \( N \) is attached in a vertical position.

A second mirror \( M \) is permanently fixed to \( E \). The images of the scale from both mirrors are seen side by side in the telescope. An index mark is taken on the image of \( M \) for reading the movement of \( N \). By this means allowance is made for any movement of the test piece and extensometer as a whole, relative to the position of the telescope.

With the instrument as used by Morrow the extension of the specimen is obtained to the nearest \( 0.00005 \) of an inch.

Other single mirror extensometers have been designed by Unwin,\(^3\) Martens,\(^4\) and Hartig.\(^5\)

§ (54) Compressometers. — Most instruments used for tensile experiments can also be used as compressometers provided that the test piece is of sufficient length to take them. It is, however, often necessary to modify the method of attachment. The conditions applicable to the use of extensometers (§ (53)) apply, with just as much force, to compressometers.

The Yeh extensometer (§ (55)), using double micrometer screws, and the Wisconsin (§ (59)) dial extensometer are both used in the U.S.A. for compression tests by a suitable modification of the clamp.

Ewing's compressometer for short blocks (Fig. 80) is on the same principle as that used for tension tests. The mechanical multiplication is, however, increased to five times, enabling readings of \( 125,000 \) of an inch to be obtained.

Martens's mirror arrangement (Fig. 76) has been used by the author as a compressometer on diameters up to \( 4 \) in. by providing additional springs \( S \) to hold the clips on to the larger size of test piece.

Unwin \(^6\) has designed an instrument for short blocks combining lever and microscope.

---

\(^4\) Handbook of Testing, part I, p. 500.

\(^5\) Civ. Engineer, 1863, part IV.

This instrument is shown diagrammatically in Fig. 81. The lever $L_1$, having a knife edge resting on the pillar $P$, gives a mechanical magnification of $2$. The frame $L_2$ is fixed to the specimen by four screws, and both frame $L_2$ and lever $L_1$ carry silver plate on their ends having a fine scratch on each. The distance between these scratches is measured by the micrometer microscope $M$. Alterations of this distance with load give the compressive strain as the mean of that on the two sides of the block.

§ (50) Torsional Stress Indicators.—For measuring plastic deformations in torsion, in order to determine the coefficient of rigidity, accurate observations are necessary. All instruments for this purpose should be independently fixed on the bar with a definite gauge length.

Where a high degree of accuracy is not essential, a convenient and simple method is to clamp two long pointers on to the specimen at a given distance apart and observe their movement over a fixed scale. The difference between the readings is a measure of the torsional strain.

(i.) Porter's Torsion Indicator. In this indicator the long pointers of the above instrument are replaced by two rings clamped to the test piece at a gauge length of 3 in. by three set screws. One clamped ring is graduated in degrees and carries on it a concentric ring engraved with a vernier reading to five seconds of angle. The vernier ring is supported on ball bearings and is operated by an arm fixed to the second clamped ring. Provision is made for setting on to the cross wire of the vernier frame.

When the torque is applied to the test piece the cross wire moves relatively to the microscope, and the amount of this movement measured by the micrometer gauge is about one second of arc. When the torque has exceeded the range of the gauge cross wire can be readjusted to zero by moving the cross-wire arm round the circular plate means of a tangent screw.

(ii.) Unwin's Torsion Micrometer. This instrument acts on the same principle as designed by Porter. There are, however, or two slight differences in detail. Unwin's method the microscope, attired to a projection from one clip, sights on a finely divided scale on the other clip gauge length of 5 in. The micrometer piece reads to 0.005 degree.

(iv.) Mirror Torque Indicator. The method employed at the N.P.L. is shown in Fig. 82 consists of two small clips, $A_1$ and $A_2$.

---

1. Amer. Soc. Test. Mat. x 578.
fastened to the test piece by three pointed set screws C. Attached to these clips are the adjustable mirrors B_1 and B_2 of a Marcus mirror extensometer. The mirrors are arranged, on a gauge length of four inches, so that they are in the vertical plane passing through the axis of the test piece. The method of measuring the movement of the two mirrors by the use of a single telescope has already been described (§ 53). The difference between the readings from each mirror at small increments of the torque gives, when multiplied by a constant depending on the scale distance, the angle of twist for that increment on a length of four inches.

§ (56) DEFLCTIONMETERS.—These instruments are used to measure the amount of bending of beams, etc., during a transverse test.

Commercially a multiplying lever deflectionmeter (Fig. 60) is generally employed or a strained-wire arrangement may be used where large deflections are to be measured. This is shown in Fig. 83. A fine wire W is strained between two pins fixed on the neutral axis of the beam above the supports and kept taut by a rubber band R. This forms a datum line. A polished scale S is graduated either in mm. or inches and suspended from the neutral axis at the centre of the beam. The observer brings his eye to such a position that the wire and its image in the polished scale coincide, and he then reads the position of the wire on the scale.

For most work an accuracy of 0.001 in. is usually sufficient.

The methods described above do not fulfill some of the essential conditions for accuracy, which are:

1. The apparatus should be designed to give the relative deflections of points in the neutral axis of the beam. This requirement is not fulfilled by the lever deflectionmeter.

2. The mean deflection should be obtained. The apparatus should either provide for taking readings on both sides of the test piece or automatically give the mean deflection. This condition is not accomplished by the strained-wire arrangement.

§ (57) APPARATUS FOR MEASURING LATERAL STRAINS. (1) Coker's Lateral Strain-measuring Apparatus.—This instrument is shown diagramatically in Fig. 84 and consists of two tubular arms A_1 and A_2 connected by a flexible steel plate B which forms the fulcrum. The steel plate is gripped by two collars C_1, one of which carries an adjustable screw L_1 which bears on the test piece and keeps the instrument from turning. The arms are attached to the test piece T by two screws DD, the pressure on which is provided by the compression of a spiral spring S on the opposite side of the fulcrum.

The arm A_2 has a projection H, the end

Bag, See, Edinburgh Trans, xxv. part i. p. 422.
ELASTIC CONSTANTS

of which is opposite to the arm $A_1$ and is
arranged to spring towards $K$, gripping a
half-edge $J$.

Any change in the diameter of the test
piece causes a relative movement between the
end of the arm $A_2$ and the projection $H$ of
the arm $A_1$. This movement rotates the knife
edge $J$, to which a mirror $K$ is attached.
The rotation of this mirror is observed by a
telescope and scale and gives a measure of the
alteration in the diameter of the test piece.

![Diagram](image)

The scale distance is arranged so that each
scale division represents 0.000001 in.

(3) *Morrison's Instrument for measuring the
Lateral Contractions of the Bacterium*.—This instru-
ment, shown diagrammatically in Fig. 85, also
uses optical means of measuring the
relative displacement of two arms.

Two arms $KK$ and $LL$ are pivoted at $F$
and two screws $A$ and $B$ grip the test piece $T$
and are pressed inwardly by stiff springs $C$.
Alteration in the diameter of the test piece
causes arm $K$ to fall relatively to the arm $L$.
This relative motion is measured by the tilt
of a mirror $M$ which is supported on three
points, two of which rest on arm $L$ and one
on arm $K$. A vertical mirror, not shown,
is also fixed to $L$ at the side of the tilting
mirror $M$ and serves as an index for that
mirror, thus eliminating any errors due to the
instrument moving relatively to the observing
telescope. The instrument is balanced by a
weight $W$.

§ 59 (58) CALIBRATION OF DEFORMATION-
MEASURING APPARATUS.—The usual methods

of obtaining the constants of extensometers,
compressometers, etc., are:

1. By measurement of the leverage of the
instrument. In some types of apparatus this
may be carried out successfully. With the
Martens mirror extensometer the constant
depends on the width of the rhombus and the
scale distance. The former can be determined
by an accurate measuring machine, and the
latter is usually adjusted by setting the scale
distance from the test piece by means of a
gauge of known length.

2. By test on a steel test piece whose
elastic constants have been accurately deter-
mined. The test piece is gripped in the
testing machine in such a way that the stress
is distributed in the proper manner and
readings of the apparatus which is to be
calibrated taken at definite increments of the
load. These readings are then compared with
those calculated from the known elastic con-
stants. If possible, a standardised apparatus is
attached to the test piece at the same time
as the one whose constants are unknown and
a direct comparison made.

3. By a calibrating instrument. An instru-
ment used by the author is shown in Fig. 86
and consists of a stand $D$ carrying two
arms $B_1$ and $B_2$. These arms are movable
along a feather on the stand so that their
position can be adjusted. They are fixed
accurately in line to take two rods $A$ and $B$,
should always be approached in the same direction in order to eliminate any backlash in the screw. As the accuracy of the calibration depends upon the accuracy of the screw, this has been determined on a screw-measuring machine and a correction curve obtained for it.

§ (99) AUTOGRAHIC RECORDING APPARATUS. — The deformation co-ordinate of the curve is always recorded directly from the test piece itself, usually with some form of multiplication. The main difference in the various types of recorders is in the method of obtaining the load co-ordinate. There are two principal ways in which this is done:

(i) Load recorded by the movement of the counterpoise, either with or without automatic adjustment.

(ii) Load co-ordinate obtained by the deformation of a calibrated spring.

The early diagramming apparatuses were applied to pendulum machines. Thurston, in 1876, designed the torsion test apparatus described in § (10), and, in 1877, Abbott constructed a recorder adapted to a machine in which the pull from a hydraulic press is transmitted through the test piece to a pendulum, the angular rise of which gives a measure of the load. An improved apparatus of the same kind was used by Pohlmeier in 1882, and more recently by the N.P. E. for tests of copper and brass wires fully described in the British Engineering Standards Association Report, No. 55.

§ (99) AUTOGRAHIC APPARATUS, RECORDING FORCE OF COUNTERSKORE. — In machines having a moving counterpoise the load co-ordinate is obtained from the position of the counterpoise on the beam by moving a drum or pencil, by suitable pulleys or gearing, from the shaft or screw which drives the counterpoise. This beam is usually kept floating by moving the poise by hand adjustment. By this means, however, the reduction in load at the yield point cannot be obtained and the final reduction, when the test piece is stretching locally, is only imperfectly reproduced.

Riehle Autographic and Automatic Apparatus. — In some American machines an autographic apparatus is provided having an automatic weighing device. This device is designed to move the poise on the beam automatically to balance the load on the specimen. In the Riehle machine the scale beam on rising or falling completes an electric circuit at the top or bottom stop in the beam stand. Each circuit is separate and connected to a magnet.

The driving pulley of the machine turns a horizontal shaft which has a cast-iron disc on its end. This disc in turn drives one of two fibre wheels located equidistant on either side of the centre of the disc. Each fibre wheel has an armature controlled by one of the magnets of the electric circuits mentioned above. Thus when the beam rises and completes the top circuit, one of the magnets attracts its armature, causing one of the fibre wheels to engage with the cast-iron disc and drive the poise along the beam and so balance the load. When the beam drops and hits the lower contact, the armature of the other fibre wheel is attracted by its magnet, which brings this fibre wheel on to the cast-iron disc and drives the poise in the opposite direction.

The screw which drives the poise also, through gearing, drives the recording pencil axially along the drum, so that the tracing of the load, which is recorded, corresponds directly to the load weighed.

The other coordinate is obtained by the drum revolving proportionally to the deformation. "Fingers" rest on top of U clamps fastened to the specimen by hardened steel-pointed set screws at the correct gauge distance. The lower "finger" moves downwards as the test piece extends and by means of a rack and pinion converts this motion into a rotary one revolving the drum through mitre wheels. The actual extension is magnified five times. The fingers are so arranged with clamps on telescopic tubing that only the extension between the U clamps is recorded on the diagram.

§ (91) AUTOGRAHIC APPARATUS USING A CALIBRATED SPRING. — (i.) This method is used in two Wickstead recorders. In the earlier apparatus 1 the measurement of the stress is entirely independent of the position of the poise on the beam, but is taken as being proportional to the compression of a helical spring acted upon by an auxiliary plunger operated by hydraulic pressure from the straining cylinder of the testing machine. As the load is applied by the straining cylinder it is balanced by running the poise along the beam, and the hydraulic pressure in both the straining cylinder and the auxiliary cylinder increases. The auxiliary plunger therefore compresses the spring, and the amount of the movement of the spring is recorded by a pencil on the recording paper in a direction parallel to the axis of the drum. The drum is also given a rotation proportional to the extension of the test piece and an automatic diagram is thus drawn.

The auxiliary plunger is operated during the test in order to eliminate the friction as far as possible. The yield and maximum loads are noted from the position of the counterpoise, in order to fix the load scale of the diagram. (ii.) The Buckingham Wickstead Patent Spring Balanced Recorder is entirely automatic, the variations in the resistance of the specimen are accurately recorded. The action of

the recorder is shown diagrammatically in Fig. 87. The counterpoise \( W \) is placed at the end of its travel, thus extending the spring \( S \). As the load \( W \) is applied to the test piece an equivalent load is released from the spring \( S \), which therefore contracts. The amount of this reduction in length is proportional to the load on the test piece and is registered on the recording drum \( R \) by means of a cord \( C \) passing over fixed pulleys \( P_1 \) and \( P_2 \) and attached to the pencil \( D \) of the apparatus.

The load is thus recorded axially, and the drum is rotated by the movement of the lower pulling load relatively to that of the upper shackle, to give the deformation co-ordinate. As the deformation is not communicated from a fixed gauge length of the test piece, it includes movement in the grips and cannot be taken as the extension of the specimen.

Full details of this recorder are given in Kennedy's paper to the Institution of Civil Engineers, and the following description of the principle of the apparatus is also taken from that paper:

The test piece \( a \) is placed in the machine in series with a stronger bar \( B \), called a spring-piece, and the two, which are connected directly by a simple coupling, are pulled simultaneously, the one through the other. The spring-piece is of a material such that its limit of elasticity occurs only at a load greater than that which will break the test piece. It must also be of material ascertainned by previous experiment to be perfectly elastic, so that its extension is strictly proportional to the pull on it, and therefore to the pull on the test-bar. By a simple arrangement a very light pointer \( c \) is made to swing about an axis through an angle proportional to the extension of the spring-piece, and proportional therefore to the pull on the test-bar. The end of this pointer in its motion always touches a sheet of smoked glass \( d \) to which is given a travel—in its own plane—proportional to the extension of the test piece, and in this way the diagram is drawn. By an arrangement of differential levers it is assured that the motion of the glass depends solely on the extension between the marked points on the test-bar, so that no amount of extension of the coupling, in the ends of the test piece, or in any other part of the apparatus, can move the glass. The apparatus is also so arranged that the absolute elongation of the spring-piece does not cause any motion of the pointer relatively to the glass."

(v.) Dalby's Optical Recorder.—This apparatus is shown diagrammatically in Fig. 88. It is similar to the Kennedy-Ashcroft recorder in that the load is obtained from the extensions of a bar acting as a very stiff spring, but whereas Kennedy uses mechanical means of increasing and transferring these extensions

---

to the diagram, Dalby adopts an optical method and thus obviates the possibility of inertia errors.

The spring-piece $W$, seen in Fig. 90, is hollow and is cemented at its upper end to the shackle $A$ of the testing machine. A projection through the shackle is mounted in a light-tight box $B$. The ray from a point of light $Z$ is reflected by a fixed mirror $Q$ on to a concave mirror $M$, which again reflects it on to a third mirror $N$ and thence to a photographic plate at $P$, where it is accurately focused.

The mirror $M$ is supported on three points; two of these, about which the mirror can tilt, are in contact with the hollow spring-bar, while the third rests on a cup on the top of the central rod $T$. Any stretch of the spring-bar $W$ will cause it to move relatively to the central rod $T$ and thus tilt the mirror $M$. This tilt will cause the point $P$ to move horizontally across the photographic plate, a distance of 340 times the stretch of the bar.

The mirror $N$ is rotated by the linkwork $G, L, V, U$ proportionally to the stretch of the test piece between the gauge length $G$; and this movement displaces the point $P$ vertically up and down on the photographic plate. The point of light therefore traces on the plate a stress-strain diagram of the test made. After development the relation between load and extension can be measured from the plate with great accuracy.

V. DETERMINATION OF THE ELASTIC CONSTANTS

The complete load-extension diagram is drawn by means of some form of autographic diagram apparatus, but for the accurate determination of the elastic limit and modulus of elasticity it is necessary to determine with extreme accuracy the deformations produced by small loads.

§ 62 The Elastic Limit.—The elastic limits in tension and compression obtained from stress-strain curves on the first loading of a piece of material such as steel are not constant for the material but depend upon the previous treatment that the material has undergone. They are called the "primitive" elastic limits to distinguish them from the "natural" elastic limits set up in the material when it is subjected to a few alternations of stress.

The definition of the elastic limit which has been standardized by the British Standards Association is accepted in this case:

The elastic limit is that point of stress at which the material, if strained very slightly, will return to its original length. When a material is stretched and then relaxed, the amount of strain disappears if the stress is not too great. The point at which this strain disappears is the elastic limit. For most materials, it is difficult to determine this limit with accuracy.
the stress so small that when it is removed
the material regains its original dimensions
(i.e., that there is no permanent set). Hence
the elastic limit is occasionally defined as the
maximum stress below which the material
would fully recover its form upon removal of
the load. This may be called the "E" Limit.
With most materials the two definitions give
substantially the same results, they both re-
quire delicate extensometers for their deter-
mination, but the method of procedure during
the test is slightly different.
In the first case extensometer readings are
taken with gradually increasing loads and the
results plotted as a load extension diagram.
The point at which there is a deviation from
Hook's Law is clearly indicated, and the Module
of Elasticity can be calculated from the slope
of the elastic line. The increments of load
taken are usually about \( \frac{1}{2} \) of the estimated
value of the "E" Limit, and if the value of
the "E" limit is known to a first approxima-
tion, the increments are made smaller in the
neighbourhood of that value and until the test
is completed.
The following measurements (Table 21) are
taken from a specimen machined from a piece
of boiler plate and show how the "E" limit
and the modulus of elasticity can be calculated.
The results are plotted in Fig. 91 and show
that the limit of proportionality is at 10 tons
per square inch.
From the elastic line it can be seen that at
a stress of 12-3 tons per square inch the ex-
tensometer reading is 291; this is equivalent
to an extension of 0-001 in. on 1-0 in.
The strain is therefore 0-001 and the modulus
of elasticity
\[
\text{modulus of elasticity} = \text{stress/strain} = \frac{12-3}{0-001}.
\]
\[
=12300 \text{ lb/in.}^2 = 29-8 \times 10^6 \text{ lbs per sq. in.}
\]
If the readings of the extension and the
applied load are known to sufficient accuracy,
the limit of proportionality can be ascertained
with more precision by calculating the elastic
extension for the various loads applied, and
plotting the difference between this and the
natural extension as ordinates with the loads
as abscissae. Table 21 shows this calculation,
and the results are plotted in Fig. 92.

1. Unit = 1-254,000 lb.; i.e., 0-1 unit = 0-01 lb.

Results of tests:
- Elastic limit = 10 tons/in.
- Yield stress = 20-2 tons/in.
- Ultimate stress = 26-0 tons/in.
- Modulus of elasticity = 29,870 × 10^6 lbs/in.
- Extension = 30-9 per cent.

![Graph](image)

**Fig. 92.**

It is of first importance that shocks and
vibrations should be avoided during the applica-
tion of the load in an extensometer test,
since actions of this kind seriously affect the
sensitivity and the accuracy of the instrument.
ELASTIC CONSTANTS

The second method of procedure, employed to determine the "R" limit, is to apply an increment of the load and upon its release measure the amount of the permanent set, if any. The load is then doubled, and the set on release again measured. A further increase of the load is applied and released, and the operation repeated until a well-defined and increasing permanent set is obtained.

The amount of the permanent set is plotted against the load and an estimate obtained, from the curve, of the point at which the material starts to have a permanent set. From this reading the "R" limit is calculated.

Results show that the actual location of the elastic limit depends on the sensitiveness of the apparatus used, low results being obtained with instruments of high sensitivity. The determination of the "R" limit requires considerable time to carry out, but indicates plastic yielding of the material at an early point when it is properly ascertained.

(1) Elastic Limit by Change of Temperature.—If a material behaves elastically, increasing load produces a healing of the test piece, but if, however, a permanent set is produced, work is done in internal friction and the temperature of the test piece rises. E. Rasch,1 of Gross Lichterfelde, has carried out some experiments to determine the temperature-load curve for materials. For temperature measurement he uses thermo-couples of iron-constantan, copper-constantan, or silver-constantan bound to the test piece. Alterations of the temperature are read from the movement of a galvanometer. No finds well-defined points of inflection in his curves. The loads at which these points occur give an elastic limit, sometimes called the thermal or "T" limit.

(2) Effect of Overstrain on Elastic Limit and Yield Point.—Bauschinger found the effect, on the limit of proportionality, of overstrain to be as follows:

(1) If the limit of proportionality was exceeded but not the yield point, then the former is raised even if the test piece is immediately relaxed.

(2) If the yield point is exceeded, immediate reloading gives a lower limit of proportionality, but reloading after a long interval of time may give a raised limit of proportionality. James Muir2 found that this effect can be accelerated by immersion for a few minutes in boiling water.

Bauschinger also found that the effect on the yield point was that if the yield point was exceeded, then subsequent reloading gave a new yield point raised to the stress to which the bar was loaded in the first place. This effect occurred even if the bar was relaxed immediately, but if there was an appreciable interval of time before the reloading the new yield point might be higher than the maximum stress applied in the first loading.

§ (66) The Modulus of Elasticity.—The modulus of elasticity is the number by which the amount of any specified stress or component of a stress within the limits of elasticity must be divided to find the strain or any stated component of the stress which it produces.

There is a modulus of elasticity in tension, compression, and shear.

The modulus of elasticity in tension, denoted by E, is sometimes called the modulus of direct elasticity, or Young's modulus. The value in compression is generally the same as that in tension.

The modulus of elasticity in shear, denoted by G, is called the modulus of transverse elasticity, or the modulus of rigidity.

The moduli C and E are connected by the equation

$$ C = \frac{E}{2(1 + \nu)} $$

where \( \nu \) = Poisson's ratio.

There is also a volumetric modulus of elasticity, sometimes called modulus of elasticity of bulk or modulus of cubic compressibility and denoted by K. It is the number by which the stress upon the exterior of the substance must be divided to give the diminution in volume of cubic strain.

If E and G are known, K can be calculated from the formula:

$$ K = \frac{CE}{6G - 3E} \quad \text{or} \quad K = \frac{E}{9(1 - 2\sigma)} $$

§ (64) Modulus of Direct Elasticity.—An example of the method of determining the modulus of direct elasticity (E) is given in § (62). Some materials, e.g., cast iron, muriatic, and concrete, have no elastic line and therefore no definite modulus of direct elasticity. It can, however, be considered to be the reciprocal of the slope of the stress-strain curve at zero stress, but where the curvature near the origin is sharp this value of the modulus is of little use except as a comparative value of stiffness.

An example of a stress-strain curve with no definite elastic line is given in Fig. 29. The initial modulus of direct elasticity is obtained from the slope of the tangent (OA) to the curve at the origin.

For concrete, an empirical modulus is sometimes used for design calculations. The value is obtained in one of three ways:

(i) The "tangent" modulus (E) is obtained from the slope of the tangent to the stress-strain curve where the ordinate is the working stress—25 per cent of the compressive strength is usual for the working stress—that is, from the tangent CD (Fig. 93).

2 Roy. Soc. Phil. Trans., 1900, cxvii. 1.

* See "Elasticity, Theory of," § (66).
(ii.) The "sine" modulus (E) is obtained from the slope of the line OH, where \( H = B - \theta \) is the working stress of the material.

(iii.) The "chord" modulus (E), determined by the ratio of stress to deformation, is given by the chord drawn between two points on the curve, defined by the limits of stress for working loads, i.e., from the chord EF (Fig. 83).

The tangent and chord methods give moduli of approximately the same value, which are higher than the secant modulus.

Stanton Walker has shown, from a study of curves which he obtained from various samples, that the stress-strain curve is represented by a curve of the type

\[ S = \frac{Kd^a}{E} \]

where

- \( S \) = unit stress in concrete,
- \( d \) = unit of deformation,
- \( K \) = constant depending on strength,
- \( a \) = an approximately constant exponent,

and the relation between modulus of elasticity and strength of concrete is

\[ E = C^a \]

where

- \( E \) = modulus of elasticity,
- \( C \) = constant depending on conditions of test,
- \( S \) = compressive strength of concrete,
- \( m \) = exponent.

Similar equations were suggested by Bush and Morse.

Effect of Overstrain on the Modulus of Direct Elasticity.—If the limit of proportionality is exceeded the value of \( E \) for steel is lowered, in some cases as much as 20 per cent. Recovery, however, is effected by rest or immersion in boiling water.

Marshall showed that if steel is initially strained to a point within the limit of proportionality, a second loading may give slightly higher values of \( E \).

§ (05) VALUES OF THE MODULUS OF DIRECT ELASTICITY (Young's Modulus).—For carbon steels the value of \( E \) in lbs. per square inch varies between \( 28.6 \times 10^6 \) and \( 31.3 \times 10^6 \), with an average value of \( 29.5 \times 10^6 \). It is nearly the same in tension and compression, and is practically independent of the carbon content and of the heat treatment.

For low percentage nickel steels (10 cent) the average value of \( E \) is 29,500,000 lbs. per square inch, while for high percentage nickel steels and from \( 20 \times 10^4 \) to \( 25 \times 10^4 \) lbs. per square inch for white cast iron.

Further values of \( E \) are given in Table II.

§ (06) MODULUS OF TANGENT, OR MODULUS OF RESILIENCE, is the most method of determining the strain.
is by means of a torsion test. The strain is measured by some form of torque meter such as is described in § (55).

A stress-strain diagram is drawn in the same way as for direct stress but having torsional stress as abscissae and torsional strain as ordinates. The value of $C$ is then calculated from the slope of the elastic line. The elastic limit in shear is also easily located from the curve.

A series of observations by the N.P.L. mirror torque meter (§ (55)) on a piece of a shaft are given in Table 23 and the diagram shown in Fig. 94. From this diagram the limit of proportionality in shear is seen to lie with a torque of 1350 lbs.-in. corresponding to a stress of 240 tons per square inch, and

$$C = \frac{\text{stress}}{\text{strain}} = \frac{53,800}{0.00453} = 11.9 \times 10^6 \text{ lbs. per sq. in.}$$

**Note.** Stress = 240 x 2540 lbs. per sq. in.

$$= \frac{63,800 \text{ lbs. per sq. in.}}{r \text{ of radius of the test piece}} \cdot \frac{\theta \text{ of angle of twist on length } L \text{ in radians}}{0.025 \times (15)/(4 \times 57.3)} = 0.00453.$$  

For wire the value of $C$ is determined from the time of a single torsional oscillation. Bauerschinger found the value of $C$ for Bessmer steel of carbon content varying from 0.10 per cent to 0.60 per cent to range from $11.9 \times 10^6$ to $12.7 \times 10^6$ lbs. per square inch.

Platt and Hayward give values varying from $12.8 \times 10^6$ to $14.0 \times 10^6$ lbs. per square inch.

Average values of $C$ are given in Table 22, § (57). **Poisson's Ratio.** —Poisson's ratio is the ratio of lateral to longitudinal deformation, and is usually denoted by $\nu$.

An extensometer when used in conjunction with an apparatus for measuring lateral strains, such as are given in § (57), gives the value of $\nu$ for any material in the most direct way possible.

Both instruments are fixed on the test piece at the same time and measurements are obtained, of both lateral and longitudinal strains, for equal increments of load. The results are then plotted as stress-strain diagrams, and the ratio of the slopes of the elastic lines is equal to $\nu$ (Poisson's ratio).

The figures in the following table are taken from results obtained by Coker.

From the plotted values of these results given in Fig. 95 it will be noted that the curves do not pass through the first point, but the remainder of the observations lie on straight lines. The slope of the longitudinal stress-strain curve is $4 \times 10^{10}$, and the slope of the lateral stress-strain curve is $107 \times 10^{-13}$, therefore $\sigma = 107 \times 10^{-13} / 0.022$.

VI. SPECIAL FORMS OF TEST

In 1871 Wöhler published the results of an exhaustive series of repeated stress experiments in direct stress, bending, and torsion which had been carried out during the previous twelve years. A full description of these tests is given in Engineering of 1871, and a good account by Unwin,2 the most important deductions from these experiments on wrought iron and steel are:

(a) A stress below the ultimate will fracture wrought iron and steel if it is repeated many times.

(b) The range of stress and not the maximum stress, determines within certain limits the number of repetitions before fracture.

(c) For a given maximum or minimum stress the number of repetitions before fracture increases as the range of stress is diminished.

and there is a range of stress called the limiting range at which the number of repetitions is infinite.

(4) The limiting range of stress diminishes as the maximum stress increases.

Wöhler's work was continued on the same machines and continued by Speagenburg, whose results, however, were not so consistent as the original work by Wöhler.

Results published in 1866 by Baker, who had experimented with soft and hard steel (28 and 54 tons per square inch respectively) and 27-ton rivet iron, were in complete agreement with Wöhler's researches.

A considerable number of experiments on the effect of varying values of the minimum stress on the limiting range of stress have been carried out by Haigh.

In 1915 he reported a series of tests on mild steel to the British Association. These are summarised in Table 26.

</tbody>
</table>

The results are plotted in Fig. 96, from which it is seen that—

(1) When the minimum stress is zero, the range of stress is approximately 21-0 tons per square inch, i.e. a tensile stress of 80 per cent of the ultimate stress is sufficient to fracture the material when repeated a considerable number of times.

(2) When the minimum stress is less than half of the range (i.e. from 400 to 13-0) the curve approximately follows Gerzack's parabola (see § 79 (ii)), otherwise there is a noticeable deviation from the parabolic form.

Results in Table 27 give details of the observations on mild steel when the stresses are alternating (i.e. equal tension and compression). These confirm Wöhler's deductions b and c, given above.

Tests on Naval Brass by Haigh are summarised in Table 28 and plotted in Fig. 96, and show that for the brass under consideration the equation connecting minimum stress and range of stress is that of a straight line passing through the point where the minimum stress is equal to the ultimate stress. Haigh remarks that, as a rule, metals which give a considerable reduction of area at fracture have a high value of the ratio of alternating stress range (with equal tension and compression) to the ultimate stress. This usually varies between 1-20 in ingot iron and the best mild steel and 0-80 in...
§ (09) BAUSCHINGER’S THEORY OF FAILURE.

Bauschinger’s theory of failure due to repeated stresses is the only one which has received serious consideration. He shows that, with bars subjected to cyclical variations of stress, the elastic limits in tension and compression take up new positions, the range between the two limits depending on the material and the stress at the lower limit of elasticity. Thus if the elastic limit is raised in tension by overstrain it is simultaneously lowered in compression, so that for that condition of loading two new limits are set up, which Bauschinger calls the natural elastic limits. He showed, further, that the range between these limits was the same in magnitude as the maximum range of stress which could be applied to the material an infinite number of times without causing fracture.

Bairstow, in an important paper communicated to the Royal Society from the N.P.L., has given experimental results which constitute the first strong support of Bauschinger’s hypotheses.

In the testing machine used by Bairstow for the purpose of the experiments, cyclical variations of direct stress are automatically produced at the rate of two per minute in such a manner that the extensometer, which is of the Martens mirror type, is fixed to the specimen throughout the test, and in this way the whole history of the progress of fatigue is observed.

When the limits of stress are tension and compression of equal values it is found that, if the range of stress is above a definite value, the stress-deformation curve forms a closed loop, which is called the hysteresis loop, consisting of two parallel straight lines, corresponding to the variation of stress from the limits of stress towards the mean stress, and two curved portions, corresponding to the variations of stress from the mean value to the extreme values (Fig. 97). The width of this loop, which is the permanent set of the specimen per cycle, increases as the range of stress increases, but for a definite range of stress tends to a limit which is not greatly exceeded by subsequent repetitions of loading, even when this is the range at which fracture under fatigue eventually takes place. Under these conditions of stress the mean length of the specimen remains constant.

When the limits of stress are unequal the hysteresis loop is formed as before, but is not closed owing to the fact that the mean length of the specimen gradually changes because of the continual repetition of the same cycle of stress, i.e. the change of mean length of the specimen per cycle is the amount by which the hysteresis loop is enclosed. The amount of the permanent extension during the earlier stages of the breakdown becomes considerable as the superior limit of stress approaches the static yield point, and if its value, after the first considerable stretch has occurred, he plotted against the corresponding values of stress. The elastic range when the lower limit is zero is less than that with equal tensile and compressive stresses (about 15 percent with axle steel and 6 percent with Bessemer steel).

If a stress-extension curve is plotted, the extension being the value of the permanent extension reached after repeated alternations, it assumes the form found with hand drawn copper wire, which has no yield point but corresponds with the curve "continuously" of Fig. 98 produced back to the "natural" elastic limit.
(d) Recovery due to stoppage of the alternations of stress is appreciable, being somewhat rapid for some materials. Recovery reduces the permanent extension at a given load and can be greatly accelerated by immersing in boiling water for a few minutes, as suggested by Minn.¹

If an inclined line \( a_{2}a \) (Fig. 59) is taken to represent the limiting minimum stresses, and the limiting maximum stress corresponding to each limiting minimum stress is plotted on the corresponding ordinate, a curve of maximum stress \( s_{m} \) is obtained. The vertical distance between the two curves represents the limiting range of stress and it will be observed—

1. That as the limiting minimum stress increases the range decreases.
2. That if the maximum and minimum stress applied to the material fall between the two curves, then the material will not fail under a repeated stress having those maximum and minimum values.

§ (70) FORMULAE FOR REPEATED STRESS TESTS.—Various empirical formulae have been suggested to connect the limiting values of the maximum, minimum, and range of stress.

Weyraugh ² suggested the formula

\[ f_{\text{max}} = Z_{1} f_{\text{min}} \left(1 - f_{\text{min}} / f_{\text{max}}\right) \]

where the stress is wholly or partly reversed.

Lamnhard's ³ suggested the formula

\[ f_{\text{max}} = Z_{1} f_{\text{min}} f_{\text{max}} \left(1 - f_{\text{min}} / f_{\text{max}}\right) \]

where the stress is applied without reversal.

Fig. 100 is drawn plotting the values of \( f_{\text{max}} \) from the above formulae assuming the values of \( f_{\text{min}} \) to lie on the inclined line RS and

\[ Z_{1} = \frac{2}{3} \quad \text{and} \quad Z_{2} = \frac{3}{4} \]

The latter have been found to be average values for a variety of materials.

The curved line for the maximum stress limit derived from Weyraugh and Lamnhardt’s formulae is sometimes assumed to be straight, in which case one formula covers the whole field of repeated stresses.

(ii.) Gerber’s Parabolic Relation.—Gerber showed that, by plotting the limiting minimum stress as abscissa and the corresponding range as ordinate, a curve was obtained which, to a first approximation, was parabolic.

Using the previous notation, Gerber’s parabolic relation is expressed by the formula

\[ f_{\text{max}} = f_{\text{min}} + \sqrt{2 f_{\text{max}} f_{\text{min}} - f_{\text{min}}^{2}} \]

\( a \) being a constant for the material.

§ (71) REPEATED STRESS TESTING MACHINES.—All Wöhler’s tests were carried out at a speed of less than 100 reversals per minute, and a determination of the fatigue range occupied a very long time.

¹ Ing. Soc. Phil. Trans., 1900, exslit. 1; also Ing. Soc. Proc., 1900, exslit. 401.
Various machines have been constructed in order to accelerate the test.

Before describing these machines which are in constant use for this branch of testing, it is advisable to explain the usual procedure which is adopted in the determination of the limiting range of stress.

Starting with an unknown material and a machine giving 2000 reversals per minute, two methods of attacking the problem are used:

(a) If the amount of the material is small and only a limited number of test pieces can be prepared, a low range is applied to the first test piece, which is increased by about 30 per cent after ten million reversals. Increments of the same value are added to the stress range after each additional ten million reversals until the test piece fails. (If the test piece is hollow the number of reversals can be reduced to five million.) The range is then known to be between two values (assuming the material to be homogeneous). A second test piece is then inserted in the machine and a range applied slightly higher than the lower of the two previous values. This range is increased by small increments (depending upon the accuracy with which the results are desired) after each ten million reversals until failure occurs.

(b) Where at least four test pieces are available, the limiting range is approached from the opposite direction. The first test piece has a high range of stress applied to it, and from the number of reversals required to fracture an estimate can be obtained of the possible range. The next specimen is tested under a range still believed to be on the high side, and this process is repeated until a range is obtained under which the material does not break. A stress-reversals curve can then be drawn, from which the range of stress can be estimated for whatever accuracy is required consistent with the homogeneity of the material.

The method of procedure adopted will depend on:

(a) The amount of material available.
(b) The relative cost of preparation of test piece and running of the testing machine.
(c) The importance of the time of duration of tests of higher speed than 2000 reversals is required

The test piece is loaded by weight \( W \) on a scale pan \( S \), which is attached to the test piece through the ball bearing \( B \). The connection between the ball bearing and the scale pan is such that the latter can adjust itself in a vertical direction without putting any constraint on the ball bearing.

The number of alternations is recorded by a counter driven by a worm wheel from a worm cut on the machine shaft. The breaking of the test piece usually operates a switch and stops the motor; by this means the machine can be run continuously with but little attention.

A slight modification of the counting and stopping method is in some cases adopted. The counter is attached to the ball-bearing holder (by which the load is applied) and is driven by the inner race of the ball bearing. The breaking of the test piece causes the counter to cease recording, and the machine continues to run, without a test piece, until the next period of inspection.

A rotating cantilever machine which has
been running successfully at the N.P.L. is shown in Fig. 102.

With a bending test, the stress distribution over the cross-section is unknown if the elastic limit is exceeded, and the maximum stress only falls on the outer fibre of the test piece. The test piece is often made hollow, as in Fig. 103, the part under test being only a thin shell.

Machines of the rotating cantilever or Wilhler type have been used for researches described by Wilkerson, Steed and Richards, C. B. Dady, E. Rogers and Stanton and Pannell, J. O. Roos, C. E. Stromeyer, and A. Martens. They are made commercially by Alfred J. Amerol & Co., and Titmus Olsen Testing Machine Co. The latter company call them "White-Bonther endurance testing machines."

(P) Rotating Bar Machines.—This type of machine was first used by Sandecker in 1882. The method of test is shown diagrammatically in Fig. 104. The test specimen

![Diagram](image)

ABCD is subjected to a uniform bending moment while revolving on its axis. It is supported on revolving bearings at A and B, and the central portion between B and D is reduced in diameter. The maximum stress \( f_{\text{max}} \) on the test piece is calculated from the formula

\[
f_{\text{max}} = \frac{32 \cdot M}{d^2}
\]

where \( d \) is the diameter of the reduced portion. Results obtained with this method of test have been used by J. E. Howard and Rineman, and Cunningham.

(II) Direct Stress Machines.—Load applied by an unbalanced weight.

In 1902 Osborne Reynolds and J. H. Smith described a throw testing machine, for reversals of stress in which simple direct stresses were produced on a specimen by the inertia forces of reciprocating weights driven by a crank and connecting rod from a rotating shaft.

A machine of the same type was designed by T. E. Stanton and used for his work on the resistance of iron and steel to reversals of direct stress. A diagram of the mechanism

![Diagram](image)

was given by T. E. Stanton and the work was published by the Institution of Civil Engineers.

1 Engineering, 8.
2 Iron and Steel Inst., J., 1903, No. 2.
3 Iron and Steel Institution, Feb., 1914.
9 Engineering Record, Sect. 22, 1908; also Int. Assoc. Test. Mat. Proc., 1909.
12 Engineering, Feb. 17, 1906.
is shown in Fig. 105, which also explains the method of balancing the cranks.

Four masses M reciprocating horizontally are operated by four cranks C. There are therefore two independently perfectly balanced systems with cranks set 180° apart on the same shaft AB. The cranks of one system are at right angles to the cranks of the other system, so that the kinetic energy of the moving parts is thus approximately constant. There are four test pieces S, one stressed by each cranking mass.

Machines of this type, however, suffer from the disadvantage that the inertia forces end to the frame of the machine in such a way that its height can be adjusted to allow for elongation, while the lower end is attached to a frame carrying the armature A of a two-phase electromagnet M<sub>1</sub> and M<sub>2</sub>.

The electromagnet is excited by an alternating current from a generator giving a sine wave E.M.F., so that the pull is almost proportional to \((voltage/frequency)^2\), nearly independent of the air gap, which is small and pulsates with twice the frequency of the electric current.

Two small secondary coils wound on frames are fixed close to the pole faces, and the voltage induced in these coils is measured by a voltmeter and used for calculating the stress.

In order that the pull of the two magnets shall be of the same amount it is necessary that the air gaps shall be equal. A fine adjustment is provided with the machine to enable the test-piece frame and armature to be raised or lowered during a test until the current in the two coils and therefore the air gaps are equal. The coils are connected to a differential ammeter which reads zero when this condition is fulfilled.

By the use of a choking coil the voltage readings are rendered nearly independent of the frequency, over a fairly large range, so that slight alterations of frequency during a test do not alter the range of stress.
The frame carrying the test piece and armature is also attached, below the latter, to standard springs S, S. The stiffness of these springs is adjusted to counterbalance the inertia of the armature, etc., a precaution which is very desirable, as it eliminates a correction which would amount to 5 per cent of the stress range. This adjustment is effected by setting the springs, so that the moving system, without the test piece in place, vibrates in resonance with the magnetic pull.

By extending or compressing the springs an initial pull or push can be applied to the test piece so as to alter the magnitude of the minimum stress.

Thus if \( f_a \) = the alternating stress applied electromagnetically, and \( f_s \) = the stress applied by the springs, then the maximum stress \( (f_{max}) = f_a + f_s \) and the minimum stress \( (f_{min}) = f_a - f_s \). Range of stress = \( 2(f_{max} - f_{min}) = 2(f_a + f_s) \), i.e. the range is not affected by the load applied by the springs.

The voltmeter is calibrated by measuring the range of stress (photographically) by a special form of optical extensometer. This is shown diagrammatically in Fig. 108.

§ (72) Effect of Speed on the Limiting Range of Stress.—Reynolds and Smith 1 found that the limiting range of stress was smaller at speeds of 1300 to 2300 per minute than at 60 to 80 cycles per minute. Their conclusions have not, however, been confirmed by subsequent experiments.

Stanton and Bairatow, 2 using a machine of the same type, found that a change of speed from 60 to 800 did not seriously affect the range, and later, using a machine of the same type as Wöhler, they found that there was no evidence at all of any reduction in fatigue strength due to a rate of alterations of 2200 when compared with 200.

With respect to Reynolds and Smith's results Stanton says, "It seems probable that the reduction in fatigue strength noted by Reynolds and Smith as due to high rate of alterations is a characteristic of the particular mechanism used for their experiments."

Bairatow 3 says, "It may possibly be that the decreased range of stress found by Reynolds and Smith has some relation to the question of recovery, but further experiments are necessary to decide the question, as the effect of the rigidity of the testing machine has not yet been fully investigated. In two instances, at least, low ranges of stress have been traced to natural periods of vibration in the testing machine agreeing approximately with the period of repetition."

Eden, Rose, and Cunningham 4 found no speed effect between 250 and 1300 revolutions per minute.

§7.9 EFFECT OF RAPID CHANGES OF SECTION AND SURFACE CONDITION ON THE LIMITING RANGES OF STRESS.—Stan ton and Bniustow have shown that rapid changes of section have a marked effect on the resistance of materials to repeated direct stresses. The standard test piece that they used had a fillet of \( \frac{3}{16} \) inch, and for comparison with this they made experiments when (1) the fillet was reduced to 0.002 inch, (2) the specimen was screw cut with a Whitworth vee thread, and (3) the corners were left sharp.

The results are given in Table 20 and show—

1. That the resistance of all these forms are, in every case, far below the corresponding maximum limiting resistances of the materials.
2. That the resistance of forms (1) and (2) are practically the same for any given material, very appreciably stronger than wrought iron and mild steels.

The results of some experiments, made by the author using the Wiibler rotating cantilever method of test, are given in Table 30. The standard test piece shown in Fig. 103 has a radius of 0.025 inch.

The percentage reduction in the range is seen to agree with the results obtained by Stanton and Bniustow.

The injurious effect of scratches in parts of machinery subject to variations of stress in now recognised. Hough says that cracks develop from surface scratches under stresses

and that the ratio of these resistances to the corresponding maximum limiting resistances does not vary greatly for the different materials.

3. That in the case of the specimens having a sudden change of section, the percentage reduction of the limiting range appears to perceptibly lower than the normal. In some experiments carried out by the author the alternate stress range of some sprockets, shaft material was reduced from 58-0 (4-28 to -28) to 49-0 tons/sq. in. by a sharp scratched 0.003 in. deep. There seems to be no doubt that many

fatigue failures attributed to faulty material are really due to unsuitable fillets, sharp corners, or surface scratches left during the process of machining.

§ (74) RESISTANCE OF MATERIALS TO COMBINED STRESSES.—Frequent cases of the combination of stresses are met with in engineering practice, and the question of the resistance of materials to these stresses is now recognised as being of considerable importance.

Stress applications may be of three types:
(i) Simple stress or stress in one direction.
(ii) Biaxial stress or two stresses acting in directions at right angles to each other in the same plane.
(iii) Triaxial stress or the application of three stresses at right angles to each other.

With simple stresses, direct tension or compression, the practical constants (modulus of elasticity, elastic limit, yield stress, ultimate stress, Poisson's ratio) are taken as a basis for design. With complex stress distribution the question arises as to the way in which those constants are to be used, and several different theories have been expounded to account for the method of failure of materials under combinations of stresses.

The most important cases of compound stress, considered from an engineering standpoint, are biaxial.

Shear is an example of biaxial stress because it is equivalent to the combination of two equal principal stresses, one compression and the other tension, acting in directions at 45° with the shearing stress. Thus, in Fig. 109,

The stress on the plane AB, at right angles to the axis, is pure shear, the intensity of which depends upon the diameter of the bar and the torque applied. This shear is a combination of tension along the 45° plane CD and compression along the plane EF. It is well known that mild steel and wrought iron fracture, in a torsion test, across the plane AB, i.e. a shearing failure, while cast iron breaks along the plane EF (i.e. fails in tension) because it is stronger in shear than in tension.

Other combinations of biaxial stress are:
(a) The crank-shaft which is bent and twisted at the same time. This can be

1 See "Elasticity, Theory of," § (6).
ELASTIC CONSTANTS

then

\[ E_1 = S_1 - \frac{1}{\sigma} (S_2 + S_3), \]

\[ E_2 = S_2 - \frac{1}{\sigma} (S_3 + S_1), \]

\[ E_3 = S_3 - \frac{1}{\sigma} (S_1 + S_2). \]

For simple tension \( S_1 \) and \( S_2 \) may be taken as zero and

\[ E_3 = S_3, \text{i.e., } E = \frac{S_3}{\sigma} \text{ stress.} \]

which is the expression of the modulus of elasticity.

The maximum strain theory is mathematically correct if it is assumed

(a) to hold within the elastic limit.

(b) that Hooke's law is absolutely correct.

(c) that the material is isotropic.

(d) that the effect of temperature is negligible.

By taking the yield point as the criterion of failure, the variation of " \( E \) " between the limit of proportionality and the yield point is assumed to be without effect on the results.

(iil) Maximum Shear Theory.—This theory assumes that the condition for initial yielding of a uniform ductile material corresponds to the existence of a specific shearing stress, the intermediate principal stress being without effect.

This theory as originally proposed by Coulomb in 1778, refers to rupture of the material. It is adopted in Guest's \(^1\) well-known work (1890) where it is used in conjunction with the yield stress. It is approximately verified by W. Scoble \(^2\) and W. Mason.\(^3\)

We can assume that simple tension is a case of combined triaxial stresses where two of the principal stresses are zero. Applying Guest's law, the bar must fail in shear, and in this case the maximum shear occurs on a plane at 45°, and the shear stress intensity is 50 per cent of the tensile unit stress. Sceby and Putnam \(^4\) find that the correct ratio of elastic shearing strength to the elastic tensile strength is 0.56 to 0.60, and therefore state that Guest's law which assumes the value to be 66 is not a correct statement of the law of elastic breakdown. Becker \(^6\) found this ratio to be 0.56, and the author obtained a ratio of 0.60 to 0.68 for steels with ultimate strength of 23 and 30 tons per square inch respectively.

Becker, as the result of experimental work, proposes two laws of strength under combined stress, viz.:

1. That the strength at the yield point follows the Maximum Strain theory until the shearing stress reaches the value of the shearing yield point.

2. After this point failure occurs according to the Maximum Shear Theory.

This suggestion appears to fit in very well with existing experimental work.

The maximum shear stress theory has been modified by Perry to include a frictional term proportional to the stress and perpendicular to the plane of shear. He noticed that brittle materials fracture at angles greater than 45° with the cross-section and assumes that this is due to internal friction.

If \( \theta \) = the angle found experimentally, \( \mu \) (the coefficient of friction) = \frac{\tan \phi}{2} for tension and \( \phi = \tan^{-1} \frac{\mu}{\sqrt{2}} \) for compression.

For cast iron the angle (\( \phi \)) is found to be 34°, which gives a value of \( \mu \) of 0.35.

If \( \phi = 0 \), this theory is the same as the maximum shear theory, and Perry suggests that this is the case for wrought iron and mild steel.

(iv) The Maximum Resilience Theory.—Haigh \(^5\) proposes that the elastic limit of a material under complex stress is reached when the energy per unit volume attains a certain definite value. He bases this view on thermodynamic considerations, and also finds that, when considered from the experimental aspect, the results fit in with this theory better than they do with either the maximum stress, maximum strain, or maximum shearing theories.

Mallock \(^6\) considers the volume extension limit or the limit of shear as the fundamental limits of a material, and assumes that the material will fail when either limit has been reached.

§(70) Experiments on Combined Stresses.

Most experimental work has been carried out on ductile materials. Only a few experiments have been made with brittle materials and further research in this direction is needed.

Test on thin tubes in combined tension and

---

The only experiments so far carried out on combined torsion and bending were those by Stanton and Bulson. A diagrammatic sketch of the arrangement which was adopted is given in Fig. 110. In the position shown the cross-section of the specimen at $S$ is subject to a twisting moment $WD$, and to a bending moment $W$. When the head had turned through $180^\circ$ the moments were equal in amount but opposite in sign. When the head had turned through $90^\circ$ from the position shown the maximum stress was that due to a bending moment $WD$ plus that due to the direct loading, but as in all cases this stress was below the known fatigue limit of the material under reversals of simple bending, its effect was taken to be negligible, and the specimen was assumed to be subject to reversals of the combination of bending and twisting alone.

§ (78) ALTERNATING BENDING TESTS BEYOND THE YIELD POINT—The principal objection to the commercial adoption of repeated stress tests is the time and expense of conducting tests in which millions of applications of stress are required in order to obtain the result. Many machines have been designed in which the test piece is broken rapidly under alternating stresses which exceed the yield point. Such tests do not give information as to relative "fatigue" strength of materials, but have been found useful as indicating mechanical defects, incorrect heat treatment, and brittleness.

(1.) Arnold Testing Machines.—In this test, in its latest form, a test piece $\frac{1}{2}$ in. diameter and $\frac{3}{4}$ to 6 in. long is firmly fixed at one end in a vertical position in the vice of the machine. It is bent backward and forward, through a distance of $\frac{3}{4}$ in. on either side of the vertical at a height of 3 in. above the face of the dies, by a slotted steel head fixed to the reciprocating part of the machine. The length of slot is larger than the diameter of the test piece (usually $\frac{3}{4}$ in.), so that an impact or shock is introduced at each alternation of stress. The standard speed adopted is 630 alternations per minute.

The number of alternations to fracture is recorded. Arnold and other investigators improved shaping or slotting machines to perform the test.

It should be noted that, in his earlier work, Arnold used a test piece \( \frac{3}{16} \) in. square with the force applied \( \frac{1}{2} \) in. above the line of maximum stress. The deflection was \( \frac{1}{2} \) in. or \( \frac{3}{8} \) in. on either side of the vertical, and the deflection is less than \( 0.30 \) in. The change in the number of cycles required for fracture is very great even for small changes in the amount of deflection.

(b) Impact applied to the specimen has practically no effect upon the number of cycles required for rupture.

(c) At speeds of about 700 cycles per minute the number of cycles for rupture is slightly less than at speeds of about 160, but for small changes of speed this effect is practically negligible. When the deflection is small the results on the same material do not seem to be as uniform as when the deflection is about \( 0.30 \) in. or more.

(d) The condition of the surface of the specimen has an important effect upon the number of cycles required for rupture.

(iii.) Stubsby Bending Test. The principle on which the test is based is to bend backwards and forwards a test piece \( \frac{3}{16} \) in. diameter and \( \frac{1}{2} \) in. long through a fixed angle until failure, the number of bends and energy required for each bend being recorded. The test is carried out on a machine, manufactured by C. P. Voest & Co., Ltd., and shown diagrammatically in Fig. 112. A flat steel spring B has one end gripped in a vice A which forms part of the bedplate, and the other secured to a holder C in which the test piece D is fixed. The test piece is held in a handle E, \( 3 \) feet long, by which it is bent backwards and forwards through an angle of \( 90^\circ \) located by the indicators F and P. The energy required to bend the test piece is measured by the deflection of the spring B, which is recorded on the paper attached to the drum G. The horizontal motion of the pencil H is actuated by the holder G through wires L and M and the multiplying

---

ELASTIC CONSTANTS

The wire is kept taut by a spring, but this is sometimes replaced by a string hanging from the wire M which then passes over a vertical pulley. The motion of the pencil is proportional to the energy of the test-piece as determined graphically by noting the length which the pencil holds before the point of bending of the test piece moves. The energy absorbed by the test piece is therefore proportional to the length which the pencil holds before the point of bending of the test piece moves. This is the practical value of the Sankey test, as illustrated.

The wire, which is attached to the pencil, moves from one point to another, the energy absorbed being calculated from the wire M which then passes over a vertical pulley. The motion of the pencil held in the pencil holder M moves through one notch in a rack, which is attached to it so that a small movement of the pencil holder M moves through one notch in a rack, which is attached to it so that a small movement of the pencil holder may be used to measure the bending moment.

The movement of the pencil holder M moves through one notch in a rack, which is attached to it so that a small movement of the pencil holder may be used to measure the bending moment. This is shown diagrammatically.

The Sankey test is a relatively simple test for determining the strength of materials. It is particularly useful for determining the strength of materials which are not suitable for testing by other methods. The test is based on the principle that the force required to bend a wire is proportional to the energy absorbed by the wire. This is shown diagrammatically.

In this test, the wire is bent to a certain angle, and the force required to do this is measured. The force is determined by noting the length of the wire which moves through one notch in a rack, which is attached to the pencil holder. This movement is then converted into a force by a lever system.

The Sankey test is useful for testing materials which are not suitable for testing by other methods, such as metals which are not ductile. It is also useful for testing materials which are not available in the required form, such as powders or pastes.

The Sankey test is a relatively simple test for determining the strength of materials. It is particularly useful for determining the strength of materials which are not suitable for testing by other methods. The test is based on the principle that the force required to bend a wire is proportional to the energy absorbed by the wire. This is shown diagrammatically.
ELASTIC CONSTANTS

recorded by the bell-crank indicator G marking on a continuous recording paper H. The form of diagram is shown in Fig. 118a.

![Fig. 118a](image)

(v) Other Investigators and Machines.—Bond-
derall used a machine in which one end of the specimen was clamped in a vise and the free end vibrated. The vibrations were maintained electromagnetically, and the oscillations were recorded optically and photographically.

Schuhart applied wire under repeated bending. The wire was gripped in curved-faced jaws and bent backward and forwards into contact with the curved jaws.

Huntington applied alternate bending by means of an attachment to a shaping machine.

§ (79) HARDNESS AND ABRASION TESTS.—An examination of the methods employed in hardness testing shows that each of them falls into one or other of two distinct categories. These are:

(i) Indentation tests, in which the surface of the material under test is permanently distorted by the pressure of a hard steel ball, cone, or knife edge.

(ii) Abrasion or scratch tests, in which particles of the material whose "hardness" is to be determined are torn away from its surface by sliding contact with some other substance whose corresponding resistance is so high that its surface remains unimpaired by the action.

If each of these methods were a measure of the same definite property of the material which is as characteristic of it as, say, its elasticity, it would be evident that the ratio of the results of any two of the methods would be the same for every material tested. Comparisons between the results of these various tests have formed the subject of several researches which have been published during recent years. The general conclusions as summarised by Turner appear to be that, although an approximate agreement may seem to exist between the various methods when applied to the case of relatively pure metals in their cast or normal state, yet when the resistance to deformation is due to tempering or to mechanical treatment no comparison is possible.

That this should be so would seem to follow from the consideration that the resistance which any so-called hardness is supposed to measure is that which the body under test exerts against a complex distribution of stress over its surface which has partially deformed or disintegrated it, and it is evident that its value will depend, not on the stress constants of the material such as its yield point, ultimate tensile and shear stresses, but on intermediate stresses, the precise nature and distribution of which are unknown and whose ratio to the stress constants may not be the same for the same method. If, therefore, such resistance, without qualification, be defined as the hardness of the material in its broadest sense, it is clear that hardness is no more a definite quality of a material than is the strength of a piece of steel of definite dimensions. In the latter case, if the nature, amount, and distribution of the stress are known, its resistance has a definite value which can be calculated. The only difference between this case and that of the hardness test is that, since in the determination of hardness there is no possibility of estimating the stress magnitude and distribution, we are driven to direct observation of the consequences of such distribution than to a calculation of those consequences from the known characteristics of the material. Mechanical phenomena of this kind are familiar to engineers under other aspects, such as in the case of the resistance of ships and aircraft to propulsion; but whereas in these latter cases the problem is to determine the resultant force exerted by the unknown pressure distribution, in the present case, as in the corresponding one of the resistance of materials to impact, the unknown quantity is the ultimate resistance of the material to the unknown stress distribution. In all these cases, however, the practical method of solution is an experimental one, and consists of setting up a similar, or nearly similar, state of stress on a specimen of the material whose behaviour is under investigation, and noting its effects.

H. Le Chatelier says, "The problem therefore seems to be to establish two or three methods of reference for hardness, giving as widely different results as possible, so that hardness (which is an essentially complex phenomenon) may be studied under all its phases. Afterwards, for each particular application the reference method which is most applicable to the conditions may be used."

That this view is now being accepted is indicated by the development, in recent years, of what are called wear tests. For example, there are wear tests for measuring the particular form of disintegration which takes place on the surface of steel rails due to the rolling abrasion of heavily loaded wheels. The characteristics of this kind of wear are the extremely small amount of the relative movement between rail and wheel and the high intensity of the compressive stress at
ELASTIC CONSTANTS

the line of contact. On the other hand, there are wear tests of lubricated surfaces in which the pressure is relatively small and the rate of slipping large, and the same conditions of wear occur, without lubrication, with pins and check gauges.

§ (80) INDENTATION TESTS.—The indentation method of determining hardness has been applied in three ways:

(i.) By testing the material with itself.

(ii.) By pressing (statically) a harder material into the material under test.

(iii.) By punching the indentation by dropping a ball- or cone-pointed hammer on to the material and measuring the rebound of the hammer or size of the indentation.

(i.) The Material tested with itself.—Reaumur in 1722 shaped right-angled prisms from two materials which were to be compared and pressed them together. The axes of the prisms were at 90°, and the right-angled edges came into contact, forming a cross. The relative hardness was measured by the depths of the indentations.

A. Foeppl used two cylindrical test pieces of the material whose hardness was required, they were placed one on the other, with their axes at right angles, and were pressed together in a testing machine. Foeppl used the pressure per unit of flattened surface as a measure of the hardness, because he found that the surface of indentation was proportional to the pressure applied.

Haigh has recently re-introduced the test with the substitution of square for cylindrical or triangular prisms. He gives the hardness number as $H = \frac{L}{R^2}$,

where $L =$ the load
and $R =$ the length of damaged edge of prism.

Reaumur, Foeppl, and Haigh’s methods are shown diagrammatically in Fig. 114.

The necessity for the use of two test pieces is probably the reason why this method of test is not commonly applied. There is, however, no limit to the hardness of the material which can be tested, as the test is independent of the use of a harder material as an indenting tool.

(ii.) The Material tested with an Indenting Tool (statically).—Many different kinds of indenting tools have been tried and many ways have been suggested to express the relative indenting hardness.

Calvert and Johnson and Kirsch determined the load required to produce a permanent indentation of a given depth, but,

although Calvert and Johnson used a truncated cone and a depth of 3.5 mm., Kirsch employed a cylindrical plunger of 5 mm. diameter and a depth of 0.64 mm.

The test adopted in 1859 by the United States Ordnance Department was a determination of the volume of the indentation produced by a pyramidal point under a load of

10,000 lbs. A volume of 0.5 cubic inch was taken as unit hardness.

Middleberg used an indenting tool, in the form of a curved knife edge, for studying the hardness of tyres. The knife edge was $\frac{1}{2}$ inch long, had an angle of $90^\circ$, and was formed with an edge curved to $1$ inch radius. The reciprocal of the length of the indentation under a load of 10,000 lbs. was taken as a measure of the hardness.

Unwin also employed a knife edge, but in his case it was straight and consisted of a piece of hardened and ground $\frac{1}{2}$-inch square steel, $1\frac{1}{4}$ inches in length. Each tool had four indenting edges having angles of $90^\circ$. The material tested was formed into test bars $\frac{1}{2} \times \frac{1}{2} \times 2\frac{1}{2}$, and the knife edge was placed on the base at right angles to its length, overlapping it by $\frac{1}{2}$ inch on each side. The hardness number was taken as $P/H$, where $P =$ the load in tons and $H =$ the depth of the indentation in inches.

(iii.) Brinell hardness test.—The method of test devised by J. A. Brinell in 1900 is now extensively employed. A hardened steel ball is pressed under a known load into the material to be tested, and the hardness number is taken as the stress per unit of spherical area. The reason why Brinell used the spherical area is not clear, as there does not appear to be any advantage gained by using it instead of the projected area ($\pi d^2 H$).

1. L'Art de couper, 1732, pp. 295 and 296.
5. Mittheilungen des k.k. technologischen Generals-

Museum, Wien, 1891, p. 106.
ELASTIC CONSTANTS

If \( P = \text{pressure in kilograms} \),
\( D = \text{diameter of the ball used in millimetres} \),
\( d = \text{diameter of the indentation in millimetres} \),
\( h = \text{the depth of indentation in millimetres (see Fig. 115)} \),
then
\[ h = \frac{1}{2}(D - \sqrt{D^2 - d^2}) \text{ mm}, \]
and the spherical area of indentation
\[ A = \pi D h - \pi (D - \sqrt{D^2 - d^2}) \text{ sq. mm.} \]

The Brinell Hardness Number is \( H = \frac{P}{A} \).

The diameter \( d \) is usually measured by a micrometer microscope. By the use of some forms of Brinell instrument the depth \( h \) of the indentation is taken as the test proceeds (see § 67). With these instruments the depth which is measured is \( h \), and not \( h \) (see Fig. 115).

It should be noted that, owing to the rising of the edges of the Brinell indentation, \( h \) is not equal to \( h \), and, as the amount of this side extension is not the same with different materials and under similar conditions, the ratio of \( h \) to \( h \) is not always constant. It therefore follows that the hardness number obtained in this way is not the hardness number as defined by Brinell.

It is found that the hardness number varies with the diameter of the ball, and pressure employed. For strictly comparable results fixed values must be used for \( D \) and \( P \). The values standardized by Brinell are:
\( D = 10 \text{ mm.} \) and \( P = 3000 \text{ kilograms} \).

(iv) Variation of Brinell Hardness with Pressure and Diameter of Ball.—C. Benedick,\(^1\) of Upsala showed that within the range of his tests the value of \( \frac{P}{\pi D^2} \) was nearly constant, and that with a ball of diameter \( = D \), and load of 3000 kilograms Brinell’s hardness number is \( = \frac{P}{\pi D^2} (\text{Brinell number}) \).

In order to allow for variation of pressure, H. Lo Chatelier\(^2\) proposed the further modification

\[ H = \frac{P}{A} \times \frac{20000}{10^6}, \]

where \( H = \text{Brinell hardness number} \),
\( P = \text{load employed in kilograms} \),
\( A = \text{spherical area of the indentation (calculated from the diameter)} \) in sq. mm.,
\( D = \text{diameter of the ball used} \).

Both the equations suggested by Benedick and Lo Chatelier are empirical and only give approximate values.

E. Meyer\(^3\) in some published results in 1908 showed (1) that \( D = ad \), where \( a \) is a constant depending on the material, and \( d \) is a constant for a given material and given ball diameter; (2) that the mean pressure per unit area \( (\text{Ps})^2 \) is constant for a given angle of indentation, whatever the diameter of the ball.

It follows from Meyer’s law of comparison that, as \( d/D \) and \( (Ps)^2 \) are constant for similar indentations on the same material, \( P/D^2 \) is also constant, where \( P = \text{pressure} \),
\( d = \text{diameter of impression, and} \)
\( D = \text{diameter of the ball} \).

This relationship is useful when the piece of material is so small that a pressure of 3000 kilograms cannot be applied with a 10 mm. ball. It is then only necessary to use a smaller ball and a load determined by the above relationship to obtain the standard hardness number required; thus, if a ball 5 mm. diameter \( = D \) is used, the load to be applied is

\[ \frac{P}{D^2} = \frac{20000}{10^6} = 750 \text{ kilograms} \]

Some results obtained by Bakke\(^4\) and given in Table 31 show remarkably good agreement of the hardness numbers obtained in this way.

(v.) Size of Test Piece and Effect of Time on the Results and the Applications of the Brinell Hardness Test.—H. Moore found that

1. The depth of the indentation in a Brinell test should not be greater than 1/7 of the thickness of the test piece.

2. The centre of the indentation should not be less than 2.5 times its diameter from the edge of the test piece.

The time during which the pressure is applied is important. It is found that the time effect is most marked up to about 10 seconds' application of the load, but after about 10 seconds the effect is very small. Consequently, it is usual in specifications to draft the Brinell hardness test clause as follows:

“The Brinell hardness test, where specified, shall be made with a 10-mm. diameter ball and a load of 3000 kilograms, which shall be maintained for not less than 15 seconds. Prior to testing, the skin of the sample shall be removed by filing, proper grinding, or machining at the point to be tested.”

Among the most important applications of the Brinell test are the following:

1. For rapid control of chemical carbon determinations during iron and steel smelting.

2. For testing finished articles without damaging the same, such as rails, tymms, armour plates, gun-barrels of all kinds, structural steel, etc.

3. For examining the nature of the material in entire or broken parts of machinery where the making of a tensile test bar is impossible.

4. For testing the degree of hardness and softness obtainable by the thermal treatment of any steel.

5. For testing uniformity of temper.

6. For ascertaining the effect of the nature and temperature of various hardening fluids.

7. For studying the effect of cold working.

It has been shown by numerous observers (Anst., Brinell, Charpy, Dillner, Le Chatelier, etc.) that there is a close relationship between the Brinell hardness number and the ultimate tensile strength of a material.

Dillner finds that, in the case of steel, tensile strength in tons/sq. in. = C x Brinell hardness number. The values of “C” are as follows:

<table>

Unwin defined the following constants from a table compiled by Hardfield:

\[ T = 0.211 + 6, \quad Y = 0.231 - 13.5, \]

where \( T \) is the Brinell number (in kilograms/sq. mm.),

\[ T = \text{Ultimate tensile strength in tons per square inch}, \]

\[ Y = \text{Yield stress in tons per square inch}. \]

§ (81) Brinell Hardness Testing Machines.—The Brinell hardness test is quite conveniently carried out in any machine in which a pressure of 3000 kilograms can be accurately applied, such as a universal testing machine having a compression attachment, by the use of a special tool for holding the ball.

Special machines have, however, been developed for the purpose, and these are of two main types:

(a) In which the load is applied by oil pressure and measured by a pressure gauge or dead-weight control.

(b) Dead-weight or lever machines.

(1) Jackson’s Oil Pressure Brinell Machine.—An example of the first type of machine is shown in Fig. 110. This is the apparatus supplied by J. W. Jackson & Co., Limited, Caxton House, Westminster, of the Aktelokogat Alpha (Sweden) design.

The ball \( K \) is attached to the downwards acting ram of a hydraulic press. The test piece is placed on the adjustable table \( S \), and is raised into contact with the ball by the hand-wheel \( r \). The pressure is produced by a small hand-pump, and may be read directly in kilograms on a pressure gauge. The machine is also provided with a dead-weight control consisting of a piston, accurately fitted without packing, carrying a cross bar \( i \), small cylinder \( a \), and weights \( p \). The small cylinder is connected to the top of the press so that the intensity of pressure is the same on the piston as on the ram. The maximum pressure is regulated by the weights \( p \), and when this pressure is reached the
piston rises in the cylinder. The pressure remains constant as long as the piston "floats," forming a small hydraulicaccumulator.

The small piston is formed by a steel ball, and the piston rod has a cup-shaped end which presses on the ball. Any leakage of oil past the piston is collected in a receptacle from which it is returned to the reservoir through the funnel.

The pressure is released by opening a valve which connects the top of the pressure chamber with the reservoir.

(i.) Avery's Dead-weight Brinell Machine.—

The arrangement of this machine is shown in Fig. 117. The specimen is placed on the weighing platens, and if of any considerable size its weight is "tared off" by moving one of the sliding pieces upon the weighing steel-standards until the weighing system is balanced. The ball is then brought into contact with the test piece by lowering the screw by which the pressure is applied. This is done quickly by unscrewing the thumb-screw at the top of the standard, and screw by the small hand-wheel yoked to it. The thumb-screw is then screwed up tightly, to secure the locking plate and prevent the rotation of the screw. The pressure is then applied, by means of a worm and worm-wheel operated by the large hand-wheel at the side of the machine. The weight p are "set" for the prescribed load, and the lifting of the steel-standards indicates that this load is applied.

The system of levers for measuring the pressure is that adopted by W. & P. Avery, Ltd., Birmingham, in all their platform weighing machines, and is found to be extremely sensitive to small differences of load.

The leverage of the machine can be obtained directly by measurement, but it is also calibrated by dead-weight loading on the platens.

§ (82) The Johnson Hardness Testing Machine (manufactured by Brown Brothers Steel Works, Ltd., Sheffield).—This machine has been devised to ensure rapid and accurate working and at the same time withstand rough workshop use, require practically no attention or adjustment, and be easily movable from place to place without detriment. The total weight of the machine is only 100 lbs., and its over-all dimensions are 28 × 22 × 9". It will take test pieces 4½ in. thick, and the indentation can be made at distances up to 5½ in. from the edge. The arrangement of the machine is shown in Fig. 118.

(i.) Description of the Machine.—Pressure is applied to the steel ball A by means of the lever B and ball-bearing eccentric C through the single lever D and screw E. The other end of the lever D is held by an eccentric in ball-bearings F, to one of which is attached the lever G and weight H. The weight II is raised by the eccentric I when the pressure on the ball A reaches 3000 kilos, and any further movement of the
operating lever B tending to apply further pressure on the bar only results in raising the weight still more.

(ii.) Method of making Test.—The specimen to be tested (which must have a smooth flat surface) is placed on the table I. The adjusting screw E is then brought down until the steel ball A rests on the prepared surface of the specimen. The lever B is then pulled forward until the weight H rises, allowing the pawl J to fall into the toothed sector K, which will automatically prevent any further movement of the lever B. The load may be kept on for any desired length of time by means of the retaining pawl K, which is moved in and out of position by means of the knurled handle M. In order to release the pressure the lever B is replaced to its original vertical position and the adjusting screw E raised.

§ (82) BRINELL Pincers.—For ascertaining the Brinell hardness of small and thin specimens, such as cartridge cases, Rudigo Whitworth, Ltd., have devised a hand instrument which they call Brinell pincers. They are shown in Fig. 110 and consist essentially of a pair of pincers one jaw of which serves as an anvil for supporting the cartridge case C or specimen to be tested, the other jaw carrying a cylinder fitted with a piston, at the back of which is a spring. The end of the piston stem projects a short distance and carries a small hardened steel ball B \( \frac{1}{2} \) in. in diameter. A locking arrangement L enables one to adjust the compression on the spring, the usual pressure being 22 lbs.

To operate the instrument, the specimen is placed between the anvil and the ball, and the pincer handles are grasped and the pressure applied. This brings the specimen into contact with the ball, and forces the ball and piston back until the surface of the specimen comes into contact with the face through which the ball projects. Consequently, the actual pressure between the ball and the specimen is quite independent of the pressure exercised by hand.

The diameter of the indentation is measured microscopically and the readings are quite definite, even on hardened spring steel.

The instrument has been extensively employed in the manufacture of small arms ammunition. It has also been employed for measuring the skin hardness of many varieties of hardened steel articles.

§ (84) SMALL MACHINES FOR TESTING THE BRINELL HARDNESS OF THIN SHEET.

—Gardino and Banks 1 developed a "Baby" Brinell machine for testing thin sheet, using a ball \( \frac{1}{2} \) in. in diameter and a load of 15 kilograms. They found that great care had to be exercised in the manner in which the load was applied. Two methods of operation were tried, viz.:—

(1) The test piece was placed on the anvil and the ball pressed on to it until sufficient pressure was exerted to raise the balance beam.

(2) The test piece was forced, under a given load, into contact with the ball, and remained in a fixed position.

The second method gave smaller and more

consistent results than the first, and was therefore incorporated in the design of their final machine. The ball was applied by a dead weight of 1½ kgs., and the diameter of the impression was measured with a metallographic microscope with a 16-mm. objective and a thin micrometer type of eyepiece.

Similar work has been carried out in England; ¹ the ball used, however, was 1 mm. diameter.

It is essential for the measurement of small indentations that there should be vertical illumination.

§ (85) THE LHÜWK HARDNESS TEST.—In order to overcome the variation in the Brinell hardness number with load and size of ball, Ludwik ² proposed substituting a 90° cone for the ball, and this form of indenting tool is now often used on the Continent for the softer metals. The hardness number is obtained by means of this test in the same way as with the Brinell Test, i.e. the test load in kilograms is divided by the surface of the conical indentation in sq. mm., so that if

\[ P = \text{the load}, \]

and \( d = \text{diameter of indentation}, \)

Hardness number \( H = \frac{P}{\pi d^2} \times \left(\frac{d}{\sqrt{2}}\right) \)

\[ = 0.019(P)/d^2 \]

approximately.

With this apparatus the hardness number is the same whatever the load chosen, if the material is homogeneous.

§ (86) MEASURING MICROSCOPES FOR HARDNESS TESTS.—For commercial work the diameter of the indentation is measured to the nearest 0.05 mm., and for this purpose a microscope with a scale in the eyepiece is usually supplied with the Brinell apparatus. To facilitate the reading of impressions made in corners or below the general surface of the specimen, the microscope is sometimes provided with a special adaptable piece.

For research work an accuracy of 0.001 mm. is essential, and an instrument such as is supplied by the Cambridge & Paul Instrument Co., Ltd., and shown in Fig. 129, is necessary for the purpose. It consists of a microscope \( M \) clamped to a tube \( B \) which is supported by the framework of the instrument and can be traversed by the millimeter screw \( S \) having a pitch of one millimeter. The microscope is fitted with an eyepiece containing cross-wires and is provided with a special focusing mechanism.

§ (87) DEPTH INDICATORS FOR HARDNESS TESTS.—In order to dispense with the use of a microscope the depth of the indentation can be measured during the test by means of some form of depth indicator. Instruments of this type, which can be used in any compression machine, are supplied by Alfred J. Amsler & Co., Schaffhausen, ³ or the Scientific Materials Company, Pittsburgh.

The depth \( h \) (Fig. 115) is measured relatively to the original surface of the test piece. This excludes the effect of the extension around the indentation, and as the amount of plastic flow varies with different metals and different pressures the hardness numbers found in this way are not proportional to the Brinell numbers obtained in the usual way from the diameters.

§ (88) IMPACT OR DYNAMIC HARDNESS.—Numerous methods have been devised for measuring indentation hardness by the size of the indentation produced by energy of known amount. This method is complicated by a consideration of the effect of the rebound of the indenting hammer, and there is a difference of opinion as to whether the initial energy of the blow or the net energy absorbed in producing the indentation should be considered in calculating the results.

Edwards and Willis ⁴ used the initial energy in calculating the results of their research on impact hardness. Unwin, ⁵ on the other hand, is of opinion "that there should be a single impact, and that the energy of rebound should be deducted from the energy due to the height of fall in calculating hardness. He doubted the method of permitting successive impacts till the energy was expended."

A dynamic hardness test was propounded by Martel ⁶ in 1895. He used a pyramidal point as the indenting tool, and produced the indentation by the fall of a ram on to the tool. Martel found:

(1) That the work of the falling ram was proportional to the volume of the indent, and he therefore expressed hardness as the work required to produce unit volume of indentation.

(2) That for equal energies of blow the volume of the indentation was nearly the same.

The author carried out a series of experiments which confirmed the first of Martens' assertions. He showed further that, when a 10-mm diameter ball, the ratio of Brinell hardness number to the Brinell number was approximately 1.5 over a range of Brinell hardness from 20 to 600. Dynamic hardness number was taken as equal to the net energy in kilogram-centimeters divided by the volume of the indentation.

Dynamic method is useful for determining hardness values of materials at high temperatures, under which the standard Brinell test cannot conveniently be carried out. The indenting tool is in contact with the specimen for a short interval of time so that the temperature is essentially constant.

The testing machine employs a moving anvil block, designed by Avery, equipped with a 100-kilogram load. A hardened steel ball (10-mm diameter) of slightly different hardness is employed to check from time to time the readings of the Auto Punch, the latter instrument can be conveniently used in a serviceable form of impact hardness tester. It was designed for testing cast-hardened surfaces, but has proved valuable in testing materials of every grade of hardness, even pure lead.

It consists essentially of a knurled hollow cylinder C, from one end of which projects a plunger P which ends in an adapter and cap for carrying a ½-inch hardened steel ball B. The other end of the Auto Punch is closed by a screw-end, in which centrally a pawl-operating rod ½ x 3 in. is placed, of which will appear shortly. The sliding hammer is a spring which, when one of the 12-inch Auto Punches is closed, exerts about 150 lbs. pressure to compress the object, "Hardness Tests," Inst. Mech. Eng. Nov. 1916, p. 572. From ibid., April 20, 1917, 336. 374.

In a 6-inch Auto Punch spring requires about 30 lbs. The internal mechanism is shown in Fig. 121. The plunger is reduced to about ⅝ inch diameter for about 1½ inches at its inner end. This part of the plunger is small enough to pass right through the hole in the sliding hammer, and will do so when the sliding plate is moved sideways by the pawl-operating rod already referred to.

When the Auto Punch is in use the inner end of the plunger rests on the pawl in the sliding hammer. When the ball is applied to the article to be tested, and the knurled barrel of the Auto Punch is pressed towards the article, the hammer is forced back, compressing the spring, and continuing to compress it until the taper end of the pawl-operating rod presses the pawl to one side, and allows the compressed spring to drive the hammer forward until the front face of the latter strikes the end of the larger diameter part of the object. The kinetic energy of the hammer is, of course, nil up to the moment of its release, so that however rapidly or slowly the Auto Punch may be worked, the energy of the sliding hammer will be the same. This energy will be used up in deforming and heating the hammer and plunger where they strike one another, also the specimen and ball. Although the energy of the hammer is practically constant, the proportion of the total energy delivered to the specimen varies according to the hardness of the specimen. The softer the specimen, the greater is the proportion of the total energy spent in deforming it.

The diameter of the indentations produced by the Auto Punch follow those produced by the Brinell tests on the same class of material. If a Brinell Standard Block is employed to check from time to time the readings of the Auto Punch, the latter instrument can be
used as a quick way of ascertaining the approximate Brinell hardness. In cases where an Auto Punch is used to ascertain whether deliveries are to the specified Brinell hardness, it is wise to use the Auto Punch as a "workshop" gauge, and to employ the Brinell machine as an "inspection" gauge on all specimens which the Auto Punch shows to be near one or other of the limits of hardness.

§ (82) The Scleroscope 1 is a reheat instrument for measuring hardness. A small diamond-pointed hammer about 3 inch long and 1 inch diameter, weighing 1/4 oz., is allowed to fall freely from a height of 10 inches. The height of rebound of the hammer is measured against a scale, graduated into 100 equal parts, and is taken as a measure of the hardness. The shape of the diamond striking point is slightly spherical and blunt, being about 0.20 inch in diameter.

The instrument is one which depends on the production of a permanent indentation by this point, the rebound being diminished by the work expended in producing the indentation. With rubber no permanent indentation is produced, and the height of rebound is the same as that from a moderately hard steel.

The instrument is provided with an ingenious automatic head by means of which the hammer is lifted and released by air pressure from a bottle.

The Scleroscope and Brinell hardness scales 2 have been shown to be generally closely related throughout the hardness range. The Brinell hardness number divided by six is approximately equal to the Scleroscope number; the ratio appears to increase from 5:5 for soft steels to 8:0 for materials of over 700 on the Brinell scale. The applications of the Scleroscope are therefore similar to those enumerated for the Brinell test in § (80).

The Scleroscope readings have been found to be slightly dependent on the size of the piece tested. This variation can be considerably reduced by clamping the test piece to a firm foundation. Most materials are mechanically hardened by indentation. It is therefore important to ensure that the material is not tested twice on the same piece, otherwise high results are obtained.

§ (93) Abrasion or Scratch Tests.—The abrasion test has been applied in three ways:
(1) As a scratch test.
(2) By drilling or grooving with a hardened steel tool or diamond.
(3) By wearing away with or without an abrasive.

§ (94) The Scratch Test.—The scratch test has been frequently used in conjunction with an indentation hardness test. In 1722 Kieser 3 used both methods. As an indication of scratch hardness he tested metals against a bar whose hardness increased from one end to the other; the position on this bar which the metal under test would scratch indicated its hardness. Mohs 4 was the first to give a scratch hardness scale, which is still largely used by mineralogists. Ten minerals were arranged in order from 1 to 10 in such a way that each would scratch the one next below it on the list. Tale was taken as having a hardness of "one" and diamond a hardness of "ten."

(1) Turner’s Scleroscope. 5 — In this device a balanced lever is—
(1) Provided with a diamond point fixed in a vertical pencil.
(2) Loaded with a sliding weight and calibrated in order that the sliding weight can be set to represent known weights at the point.
(3) Supported in such a way that it can be rotated.

The hardness number is the smallest weight in grammes which will produce a scratch just visible to the naked eye on the smooth and polished surface of the specimen.

A series of scratches are made with diminishing weights, and the hardness is taken as the mean between the least weight which will produce a scratch and the greatest weight which will not produce a scratch.

A. Martens, 6 in order to make the test more definite, defined the scratch hardness number as the load in grammes under which a conical diamond (90°) produces a scratch 0.01 mm. in width.

(III.) The Quadrant Scleroscope.—This instrument has been devised in the Baldwin-Witworth Laboratory. The method employed is to apply a hardened edge or series of hardened edges to the surface of the test piece in such a direction that slipping occurs until they "bite" the surface of the article.

The instrument is made in various types for testing either flat surfaces, pipes, or the

4 Grundriiss der Mineralogie, 1825, Part I, p. 375.
5 Birmingham Phil. Soc. Proc., v. part II, 1897.
6 Sitzungsberichte des Vereins zur Festigung der Genterische, 1892, pp. 41 and 1890, p. 417.
ELASTIC CONSTANTS

The theory of the instrument has been worked out by H. L. Heston,1 who has shown that the angle is practically independent of the weight and size of the article to be tested. A soft bar holds the top file up so that it makes an angle of about 70°. A hard bar will not hold the top file up until the angle falls to about 15 to 20°. Hardened and tempered bars give readings between 20 and 70°, according to their surface resistance to abrasion. The instrument can also be employed for measuring the coefficient of friction between one material and another, one being attached to, or substituted for, the upper arm, and the other for the lower.

§ (99) "DWINNING OR GROOVING" HARDNESS.—S. Selvage2 measured the resistance to wear as the time required to produce in the material a cut of definite depth with a soft iron disc rotating at constant speed and pressed with constant force.

A. Hammers3 defined cutting hardness as the resistance, per square mm., to planing, when using a cutting angle of 90°.

Jaggar4 rotated a diamond point under constant pressure and at a uniform rate, and gave the number of rotations of the point to reach a fixed depth as the hardness. Bauer and Kempt5 both defined cutting hardness as the rate at which a steel drill, running at constant speed and under constant pressure, drills the material.

§ (99) Wear Tests. (a) Using an abundant or an abrasing wheel (pure abrasion).—Felix Rehin6 used cylindrical specimens (60 mm. diameter), which he rubbed under known pressure on papers covered with abrasive papers. Rosivall7 defined abrasive hardness as equal to 1 (loss of volume) divided by the amount of abrasion. Rohmer8 used a standard powdered and measured hardness by the time required to polish.

Gary9 determined the resistance to wear by the amount of abrasion caused by a sand-blast, and experimented chiefly with stones, artificial minerals, and flint. W. H. Warren10 also used the sand-blast on timber. Jametaz and Goldberg,11 and Stoughton and Maclagren12 measured the comparative loss by grinding. The latter, who also carried out indentation hardness tests, found that the two methods gave different comparative results.

(b) Wear by sliding lubricated abrasion.—Dewison13 constructed a machine in which a specimen was pressed on to the circumference of a polished wheel turning at a speed of 3200 revolutions per minute in an oil bath. The wear was measured by the loss in weight or reduction in diameter in thousandths of a millimetre after 2,000,000 turns of the wheel.

(c) Wear by dry rolling abrasion.—Sanfier14 devised a machine for testing the wearing properties of rail steel under dry rolling abrasion. In this method the specimen (D), 5 inches long and 0.5 inch diameter, was fixed in a chuck (B, Fig. 123) revolving at 4000 r.p.m. and carried over the free end of a ball-bearing (C), of inner diameter 1 inch, loaded to produce a pressure of 203 lbs. at the point of contact. The inner ring of the ball-bearing (D, 1 inch wide) was rotated by friction by the test piece, causing the latter to wear. The resistance of the material to rolling abrasion was taken as

---

6 "Irons and Steel Inst. J., 1910.
being inversely proportional to the reduction in diameter in ten-thousandths of an inch after 200,000 revolutions of the test piece.

A similar test was used by Stanton and Whittam for a series of experiments on hardness tests. The dimensions of the test piece, etc., were made slightly larger than those employed by Snaitor.

It was shown that the resistance to rolling abrasion was approximately proportional to the ball hardness number, but that the comparison was not a safe one, as there were frequently cases in which a considerable departure was found from this ratio, e.g., manganese steel which was well known to be susceptible to hardening under pressure. The results confirmed Snaitor's conclusions, and showed that what was actually measured was the resistance to disintegration of already deformed material, and that this resistance depended on the amount of deformation produced, and had little relation to the material in the unstrained condition. The method, as a means of predicting the relative resistance to wear under conditions of rolling abrasion with heavy loads, was comparatively rapid and gave the information desired.

(d) Wear by dry sliding abrasion.—The Snaitor test was carried out with high pressure and very small relative motion. Stanton and Whittam also carried out a series of tests on dry sliding abrasion, in which the amount of relative motion was large and therefore corresponding to the wear of plain collars, etc. This was done by connecting the abrading ring (diameter = D) to the chuck by means of an Obhurn coupling, so that both ring and specimen (diameter = d) completed a revolution in the same time; the line of contact remaining fixed relative to the machine. The slip per revolution was then \( \frac{D-d}{D} \) inches. The results indicated that there was very little hardening of the surface of the material under these conditions, and that the Brinell hardness number was not a safe guide in predicting the relative resistance to wear of a malleable selection of steel.

§ (97) Impact and Notched Bar Tests.—There is no doubt that the tensile test, as usually carried out, does not give all the information about a material it is essential that an engineer should know. A careful examination of a complete load extension diagram, however, reveals differences, such as those due to heat treatment and mechanical treatment, not disclosed by an ordinary tensile test, but the analysis of such diagrams requires considerable experience.

It has, occasionally, been found that a material which has satisfactorily passed the ordinary tensile test fails in practice in a manner which cannot be accounted for by errors in design. Investigation has shown that, in some cases, parts of machinery which have failed in this way have been subjected to shock. Consequently, various methods of test have been devised to give a definite indication of the shock-resisting properties of materials.

§ (98) Notched Bar Tests.—Freedom from the tendency to crack at sharp corners, when the variations of stress are considerable, is a property which is very desirable in materials for engineering work. In order to obtain this information about materials' 'brittleness' tests, in which the test piece is notched in order to limit the plane of fracture and the contraction of area, are employed.

These notched bar tests are made in tension or bending. The test piece is usually broken by a single blow in impact, and the energy of fracture obtained directly from the form of energy of the striker.

In 1900, Charpy, in a report on impact tests on metals, shows that a static tension test is more efficaciously supplemented by a notched bar bending test than by any other test, and

---

his results seem to indicate that the notched bar bending test gives information regarding the fragility of materials which other tests do not easily furnish. Charpy in the same report shows that materials which give good results with this impact test have stood well in practice, whereas the same class of materials giving low values fail, although the results from the ordinary static tensile test is the same in both cases.

The originator of this method of testing appears to have been M. Barla of Le Creusot, who in 1903 described the results of his experiments on the detection of brittleness in steel by tests on flat specimens, notched with a $45^\circ$ notch on both sides to 0-35 times the thickness, the radius at the bottom of the notch being 0-5 mm, and the total width of the specimen 30 mm. The specimen was fixed in a horizontal position between jaws, with the notch directly over the edges of the jaws and having a piece of the specimen 25 mm. long projecting from the jaws. This piece was struck by a falling weight of 18 kilograms. Each specimen was provided with a number of notches at spaces of 25 mm. along the specimen, and by making a series of tests at different heights of fall it was possible to predict the energy of blow which would just break the specimen.

It was soon realised that this method of testing revealed marked differences in the behaviour of materials which were not detected by the ordinary tensile test, and other investigators (Lo Chatelier, Charpy, Prénomont, etc.) carried out experiments, the results of which were communicated to the Congress of the International Association for Testing Materials held at Bucharest in 1911.

The report of a commission appointed at this congress to investigate the notched bar test, was discussed at the congress held in Brussels in 1904, but no advance was made in the matter of standardisation except an expression of opinion that the test gave interesting information. The German Association for Methods of Testing Materials thereupon took the matter up and issued a report in 1907, in which they recommended the Charpy method of testing. This consists in the use of a notched specimen, 30 x 30 x 160 mm., supported horizontally at the ends on knife edges of given form and struck in the centre, opposite the notch, by a pendulum. The notch was formed by drilling a hole 4 mm. diameter in the bar and sawing through from one side, leaving a depth of 15 mm. behind the notch, as shown in Fig. 124. The span is 120 mm.

The question of notched bar testing was again brought forward at the International Congress held at Copenhagen in 1908, who recommended the 30 x 30 x 160 mm. Charpy test piece, with an alternative specimen, geometrically similar but one-third of the size, where the larger dimensions could not be obtained. The matter was further discussed at New York in 1912, and the recommendations of 1900 were confirmed. No particular machine for carrying out the tests was selected, but further testing research on apparatus and test pieces of different sizes was suggested as being desirable.

The recommendations of the International Association for Testing Materials have never been fully recognised. For most test work the standard 30 x 30 x 160 mm. test piece has been found to be too large, and difficulties have been experienced with the notch of the geometrically smaller test piece.

Prénomont suggests a test piece 10 x 8 x 30 mm., placed horizontally on supports 21 mm.

---

![Test Piece](image-url)
Seaton and Jade \(^1\) carried out some tests in 1904, in which the test piece was broken by a number of blows, the test bar being reversed between successive blows.

In 1908, Stanton and Baisdell \(^2\) and Harbord \(^3\) communicated results of experiments in the Institution of Mechanical Engineers. The main point brought out by Harbord's paper was the variability in the results of individual tests of specimens of the same material. It was shown that two identical test pieces from the same bar of ordinary commercial steel gave results varying from each other by over 60 per cent. This variability has been attributed to—

1. The mode of testing.
2. The heterogeneity of the material under investigation.

Experiments published by Charpy and Comm Thomain \(^4\) show that by careful selection and heat treatment it is possible to obtain, in the course of experiments in notched bar tests, carried out on bars of steel of different nature or of copper, a degree of uniformity analogous to that obtained by means of tensile or hardness tests. Variability in the results is therefore not due to the mode of testing but to differences in the material under test.

By 1914 there was conclusive evidence that there could be large variations in the resistance of notched specimens of different materials to impact, without any corresponding variation in any of the characteristics brought out by the ordinary tensile test, and there was evidence that this variation was due to correct or incorrect heat treatment.

\(§\) (100) Impact Testing Machines. (i) The Izod Test. The Izod impact test has of recent years come into great prominence in Government specifications, owing to the great demands made by war conditions.

The original Izod machine had a striking energy of the hammer of 23 ft.-lbs., and the test piece was 2 in. long, 2 in. in wide, and \(\frac{3}{8}\) in. thick, with a vee notch 0.05 in. deep.

The present standard machine made by W. & T. Avery, Ltd., Soho Foundry, Birmingham, has a capacity of 130 ft.-lbs. The cross-section of the test piece is 10 x 10 mm, and it is notched with a 45\(^\circ\) vee notch, 2 mm deep, with a root radius of 0.25 mm.

The machine is shown in Fig. 126, and consists of a heavy base B on which are bolted two standards \(S_1, S_2\), supporting the pivot of the pendulum. The pendulum P swings on ball bearings and strikes the specimen held in the vice, cantilever fashion, its point of contact with the specimen being a hardened steel knife edge. The form and angle of the knife edge is shown in Fig. 127. The specimen is gripped in a vice V in such a

---

position that the bottom of the notch is level with the top of the vice, Fig. 128.

The specimen, in being broken, absorbs some of the energy from the pendulum, which is measured by the continued and diminished swing of the pendulum moving an idle pointer over a graduated scale. The pendulum swings less as the resistance of the specimen is greater. The scale is graduated to give the actual energy in foot-pounds absorbed by the blow. The standard three-notch test piece is shown at B in Fig. 129.

(iii) The Charpy Pendulum Machine.—The small Charpy machine has a power of about 30 kilogrammeters (217 ft.-lfs.) and a maximum striking velocity of 5-28 metres per second (17 ft. 4 in. per sec.). The principal part of the pendulum consists of the hammer M, shaped as shown in Fig. 130, and suspended at the end of a light hollow bar. The centre is suspended on ball-bearings, and an index hand is mounted with an easy frictional fit and travels over a graduated mainspring dial with the hammer when this rises up after fracturing the test specimen. The latter is held in cast-iron supports in the two uprights which are bolted down to a cast-iron bedplate.

The hammer is raised up for action by hand, and is held up by a catch operated directly by a small lever D. The drop is constant and 1-120 metres (4 ft. 7½ in.) in height. A hand brake B, worked by the hand lever C, enables the hammer to be stopped rapidly after fracture of the specimen. The weight of the falling parts, position of the centre of gravity, and heights of drop counted from the centre of gravity, are all determined experimentally. The angle of rise after pendulum is read off from the graduated semicircle. The difference between the height of fall before fracture and rising back after fracture gives the work absorbed. It is, however, necessary in research work to take into account the friction and energy absorbed by the fragments of the test specimen; the latter may be considered to take the same velocity as the pendulum itself. The weight of the test specimen being very light compared with that of the pendulum hammer, the correction is very slight and can be neglected in ordinary practice.

In order to determine the work absorbed by friction the pendulum is caused to oscillate freely and the decrease in the oscillations due solely to friction is noted down. This gives a table of corrections. The required correction can also be arrived at by noting the angle of rise of the pendulum following that causing the fracture.

A larger machine is made, and this has 200 kilogrammeters energy and a striking velocity of 7.8 metres per second.

(ii) Gallery Machine (Rotary Type).—The latest model of this machine is shown in Fig. 131. It consists of a flywheel having a "breaking knife" attached to it. This knife is arranged so that it can assume two positions:

1. Hidden in the rim of the wheel.

2. Projecting from the rim of the wheel in which position it is required for breaking the test piece.

The position is controlled by "struts" on the casing of the machine and operated by centrifugal force due to the rotation of the wheel.

The rotation of the flywheel operates a small centrifugal pump which elevates a column of liquid in a tube. The machine is designed so that when the liquid is at the top of the tube (and reading zero on the energy scale) there is 80 kilogrammeters of energy in the flywheel. When the flywheel is still, and the liquid is at its lowest level the reading is therefore 80.

The test bar is placed horizontally on knife edges which have a 30-mm. gap. The front of the machine is covered with a door which is automatically locked when the "knife" is out and the flywheel in motion.

The test is made by rotating the flywheel to a speed slightly in excess of that corresponding to the zero of the energy scale. The gear
is then disconnected and the wheel speed allowed to decrease. Immediately the liquid in the tachometer tube reads zero the “out” stud is then set “in” by pressing the “in” stud.

(iv.) Frémond Machine.—The Frémond impact machine consists of a hammer of 10 to 15 kilograms, which has on its underside a hardened steel V-shaped striker. The test piece is placed horizontally on knife edges having a gap of 21 mm., so that when the hammer falls from a height of 4 metres the striker hits it midway between the supports and exactly opposite to the notch.

Immediately after the blow of the striker the underside of the hammer, which

then only possesses the energy not absorbed by the test piece, strikes against an anvil carrying two housings provided with tempered
ELASTIC CONSTANTS

steel springs. The springs yield under the blow of the hammer and register by their deflection the energy remaining in the apparatus.

Knowing the initial energy of the hammer, the energy absorbed in fracture of the test piece is found by taking the difference.

(v.) The Amold 75-kilogravimetric Impact Testing Machine.—This machine is on the same principle as the Charpy machine, but some of the details are slightly different.

The pendulum is held up by a hook attached to a rope which is wound round a winch. The tip is released, by detaching the hook by means of a special release, and falling freely swings up on the other side of the machine after having broken the test bar. Instead of

swinging back again, as in the Charpy machine, it is held in position by a cord passing round a drum and acting as a brake.

On falling from one side, transverse (bending) tests are made, while tensile tests are made when the pendulum falls from the other side. The energy in the hammer before and after the test is registered on two movable straight scales by the movement of the pendulum. It is so arranged that the second scale raises the pointer on to the first scale and indicates the actual energy absorbed.

dition of microstructure due to faulty heat treatment.

The large variation in the energy absorbed in the Izod test due to alteration of heat treatment is well shown by the figures in Table 32, taken from a paper by Philpot.1

Some tests by the author on a piece of boiler plate and nickel chrome crank shaft are given in Table 33, and show the same kind of variability with heat treatment.

Baguelli Wild has shown that the brittloncs in steel resulting from a high percentage of sulfur and phosphorus is well marked by the Izod test. He says, "Certain steel for making nuts and bolts was found to contain sulfur and phosphorus in excess of 0.1 per cent; such steel invariably failed to give any higher reading than 2 to 5 ft.-lbs. on the Izod, whereas a steel of exactly similar composition but with similar treatment but with sulfur and phosphorus below 0.05 per cent gave an Izod test figure of over 40 ft.-lbs."

§ (102) DIMENSIONS OF STANDARD TEST PIECES.—Although there are several impact testers in Britain of the Fremon and Guillery type, the majority of the test houses use Izod or Charpy machines. The dimensions of test pieces for these machines have been standardized and are shown in Fig. 129. It will be noticed that in each case the cross-sectional dimensions are 10 x 10 mm. and that the form of notch is the same (the Guillery machine uses the same size of test pieces as the Charpy machine, while the Fremon test piece is smaller and is described in § (98)). The form of notch selected, and sometimes called the Izod notch, is a 45° vec, 2 mm. deep, with a root radius of 0.25 mm.

§ (103) THE ANGLE OF THE NOTCH.—Experiments by Thomas 1 at the Watertown Arsenal show that, with mild steel, the angle of the notch does not appreciably affect the results until it has exceeded 45°. The results that Thomas obtained are given in Table 34.

§ (104) ROOT RADIUS AND DEPTH OF NOTCH.—The 10 x 10-mm. test piece in which the notch is formed by a drilled hole 1½ mm.

diameter, proposed by the International Association of Testing Materials, cannot be produced economically on the majority of alloy steels.

The form of notch selected as a standard, viz. 45° vec notch, 2 mm. deep and 0.25 mm. root radius, does not suffer from this objection as it can be easily produced even on the steels.

The shape at the bottom of the notch has an important effect on the work absorbed in fracture, which has its least value when the angle at the bottom of the notch is as nearly zero as possible.

Results by Dix 2 summarized in Table 35, and by the author (Table 30) show this effect very clearly.

Table 34

It has been found that the sharper the notch is made, the better the test discriminates between brittle and tough materials. That is to say, that as the material tested becomes tougher the effect of alteration of the root radius is less.

It is unsatisfactory, commercially, to standardize a dead sharp notch as it is difficult

2 Proc., 1910, xii. part ii. 721.
ELASTIC CONSTANTS

207

to be always sure that it is produced. A root radius of 0.25 mm. has been selected as it is found that, with a radius of this size, the test is still effective in the detection of faulty heat treatment.

It has also been found that shallow notches increase the energy to fracture of tough materials relative to that required for brittle materials.

§ (105) Shape of Test Piece.—Philpot found that a round test piece can be produced which can be used for acceptance tests on heat-treated steels in place of the standard square specimen. The latter is, however, for the more desirable from the point of view of testing and, by properly rigging up for quantity production, it can be prepared by a pair of suitable mills just as economically as the round test piece.

§ (106) Comparison of Tests on Different Machines.—Philpot has made a comparison of tests in the Charpy (beam) and l-beam (cantilever) machines on the standard 10 × 10-mm. test piece with the 45° standard notch, 2 mm. deep and 0.25 mm. root radius. He finds that, where the energy absorbed is less than 70 ft.-lvs., notch tests, made in either the Charpy or the l-beam machines, give similar values, but where the energy absorbed in fracture is greater than 70 ft.-lvs., there is a tendency for the values from the Charpy machine to be somewhat higher.

Charpy and Curran Themul have made a series of experiments, with a steel specially prepared to give consistent results, on "beam" machines of three different types (pendulum, vertical drop, and rotary) and have found that, in regard to energy absorbed in fracture, the results are practically identical when the size of test pieces, notch, distance between supports and radii of supports and striker are uniform.

§ (107) Effect of Striking Velocity on the Energy to Fracture.—Both Behinger and Fremont have found a variation of the energy absorbed in fracture with striking velocity but in opposite directions. Charpy has found that the influence of the rate of impact is practically negligible within limits which do not exceed those of appliances generally employed in the testing laboratory.

Some tests carried out by the author show that, on a machine of the Charpy type at striking velocities up to 45 ft. per second, increasing striking velocity may either increase, decrease or maintain the energy absorbed in fracture according to the material upon which the tests are made. In any case the effect is not appreciable until after a velocity of 16 ft. per sec. is reached, as is shown by the results in Table 37.

§ (108) Slow Bending Tests on Notched Bars.—It has been shown by Philpot and others that, if a notched bar test piece is broken slowly, the work expended is comparable with that measured by an impact machine (at moderately low striking velocities) and is equally as effective in distinguishing between certain brittle and tough materials.

As an average of a large number of tests Philpot found that the energy absorbed in the slow bending test is about 75 per cent of that given by an impact test (in two or three cases the energies obtained by the two methods are approximately equal), and he attributes the difference to energy dissipated in the pendulum testing machine. The striking velocity in Philpot's impact tests did not exceed 3-5 metres per second, and his conclusions only hold up to that value.

Philpot for his slow bending tests uses an ordinary Drilled machine, and measures the
deflections of the specimen for different loads by means of a microscope. The results are plotted and the area of the curve is integrated in order to obtain the total energy absorbed. 

The Humphry Autographic Notched Bar Testing Machine, made by the Foster Instrument Company of Letchworth, is devised to carry out this class of test rapidly and conveniently and in a manner giving the maximum information as to the material in a minimum time. It is illustrated diagrammatically in Fig. 132 and photographically in Fig. 133.

The test piece A is gripped in the vice B, so that the jaws of the vice are in line with the notch in the test piece. The socket C is attached on the projecting end of the test piece, and is a reasonably close fit therein. A bending stress is applied to the test piece by means of the winch D and the wire E, which is attached to the socket C. The outer end of the spring bar F is firmly fixed to the socket C. The outer end of the spring bar is supported by two rollers G and G'. The socket C carries also a rigid bar H.

The deflection of the spring bar F is a measure of the bending moment applied to the test piece. Since the rigid bar H is not subjected to any bending moment it will move through the same angle as the socket C, and this movement will therefore be a measure of the bending of the test piece. The pen J slides upon the rigid bar H, its position being determined by the thin wires or cords K and L, which are kept taut by a light spring M. One end of the wire K is attached to a post N so that as the rigid bar H moves in consequence of the bending of the test piece, the wire K will draw the pen to the right. The point of the pen makes upon a calibrated chart P carried on the spring bar F, therefore, if the test piece offers no resistance whatever to bending force the pen would draw a horizontal line on the chart, the length of which is proportional to the angle through which the test piece is bent. As, however, the test piece does offer resistance to bending there will be a resultant movement between the spring bar F and the rigid bar H.

The pen, therefore, draws a diagram showing the relation between bending moment applied and angle of bending throughout the duration of the test. The total energy absorbed in the breaking of the test piece can be obtained from the area of this diagram.

The machine can also be fitted with an integrating device so that the energy absorbed can be read directly from the machine. This device is shown in Figs. 132-3. The wire K passes round a pulley Q. The pulley Q is attached to a spindle having at its lower end a friction disc K, so that the bending of the test piece which results in the movement of the pen to the right also results in a proportionate rotation of the friction disc K.

The under face of this disc rests upon the edge of the friction wheel, not shown. The spindle of the friction wheel is carried with the chart plate upon the spring bar F. When the bending moment is zero the friction wheel is at the centre of the friction disc, but as bending moment is applied, and there is relative movement between the spring bar F and the rigid bar H, the friction wheel travels towards the circumference of the friction disc, and is consequently rotated. The rotation will be proportional to the product of the bending moment applied and the angle of bending of the test piece, and this device will therefore integrate the total energy absorbed in breaking the test piece. Mounted upon the outer end of the spindle which carries the friction wheel is an index disc S which can be calibrated to read direct in ft.-Ibs.

§ 100. EARTHQUAKE SHAKES ON DIFFERENT SIZES. A trustworthy relation has not been found between the energy to fracture in test pieces of different sizes; there is, however, evidence that it is probably different on different materials. This is shown from an
Elastic Constants

examination of the results in Table 38, which gives the results of notched bar impact tests on two different steels with geometrically similar test pieces.

</table>

* The notch for the 10 x 10 test piece was a 45° cone, 0-25 mm. root radius and 2 mm. deep. The notches for the larger test pieces were geometrically similar.

It will be noted that:
(1) The energy absorbed is not proportional to either the square or the cube of the dimensions of the test piece.
(2) With the 10 x 10-mm. test piece, steel A absorbs 3.7 times the energy that steel B does, but with the 63 x 63-mm. test pieces it is only 1.5 times.

There is apparently a scale speed factor in the law of resistance of notched specimen to sudden shock which appears to be of extreme complexity.

§ (110) Tests on Unnotched Bars.—With geometrically similar unnotched test bars, either tensile or tensile test pieces, the energy absorbed in fracture for the same material is proportional to the volume of the test piece.

Heit, in 1904, as the result of some experiments in dynamic tension, came to the conclusion that, for steels, there is little difference in the total elongation and the work in fracture whether the fracture is brought in 10 minutes or 0.01 seconds. Stanton and Beimlow in 1908 and Dolevlow in 1909 (using a drop hammer type of machine) have also shown that the tensile impact test (i.e. dynamic tensile test) gives numerical values which agree with the results of the static tensile test.

Blount, Kirchhly, and Smiley, in the summary to their paper on steel testing methods, say that "the impact tensile test gives the ductility in the same terms as the static tensile test, namely, elongation and contraction of area, but always with higher numerical values. The breaking stress of the material can be inferred, but must be reduced by a factor in order to obtain the same numerical value as given by the static test; also it only gives the breaking stress. The energy absorbed per cubic inch does not vary greatly with the various types of steel; it is approximately 50 per cent more than that obtained by the static tensile test, and is also a definite criterion of the type of the steel; at any rate, of normal steels containing a small proportion of phosphorus. From the experiments referred to by Heit, it would appear that steels containing an undue proportion of phosphorus give a much smaller energy per cubic inch with impact tensile tests."

§ (111) Tests Under Repeated Bending Impact.—In 1908 Stanton carried out extensive investigations on the method of testing by repeated impact, and devised a machine to reproduce stress conditions which are met in certain machine parts in actual use, where the effect of alternating blows is produced on the material at positions where there is a rapid reduction of cross-section. The test bar, 0-500 inch diameter and 0-5 inches long, is supported on knife edges 4¼ inches apart. The test piece has a groove turned round the centre of the span 0-05 inch deep, so that the effective diameter at the bottom of the groove is 0-400 inch. The groove is in the form of a vee, whose angle is 50° and root radius 0-01 inch. The test piece is fixed in the machine, where it receives blows at the rate of about 30 per minute from a hammer whose weight is 47-1 lb., and of which the height of fall is adjustable.

6 Revue de métallurgie, 1908, p. 527.
Between each blow the bar is turned through 180° and the test is continued until failure of the test bar. The number of blows to cause failure is recorded by a counter.

A series of tests is usually made on each material with varying energies of blow, and, by plotting the energies of blow against ordinates and the number of blows to fracture as abscissae, a curve is obtained from which useful information as to both the impact strength and fatigue strength of the material can be obtained. In Stanton’s original paper it is clearly stated that when the number of blows is less than 500 the results approximate to those of the single blow impact test, and that, when the number of blows for fracture exceed 100,000, the results are in the order of the fatigue ranges of the materials as determined in a Wohler test. During the war it has been a common practice to compare materials by the number of blows required to cause fracture when the height of the fall of the tup is kept constant. As the height of fall selected causes fracture after from 1000 to 6000 blows the results cannot be properly interpreted.

The results from tests on steel correctly and incorrectly heat-treated are given in Table 30 and plotted in Fig. 134. It will be noted that the incorrectly heat-treated bars are considerably weaker as regards notched bar impact, but slightly stronger under fatigue.

The test bar previously described is the one adopted by Stanton for his research, and has a notch very similar to the standard load notch, which is easily reproduced. A notch 0.05 inch wide and 0.05 inch deep, with parallel sides and practically sharp corners has been sometimes used in conjunction with this test.

The Eden-Foster machine, manufactured by the Foster Instrument Company, Letchworth, is a close copy of Stanton’s original machine and embodies its principal features.

The illustration (Fig. 135) gives a general idea of the external appearance of the machine. The main spindle, not shown in the illustration, projects through the side of the box casing, and is driven by an electric motor with suitable gear or worm reduction. About 0.1 horse-power is required to drive the apparatus.

The main spindle carries a dog clutch driving a cam, which has a roller bearing on its upper surface and attached to the lower end of the rod H. Fixed on the rod H is an arm J which engages with the lower face of the hammer M; thus, when the rod H rises by rotation of the cam, the hammer M is lifted. The guides for the hammer consist of two sets of three point screws carried by two castings attached to the standard G and its follow on the opposite side.

Mounted on the standard G is a sleeve W, free to rotate about the standard, but normally held in a fixed position by a spring L. Clamped on the sleeve W is an adjust-

Air is nearly always used for the gas bath, but it causes oxidation of the test sample, and for special cases the test may be carried out in carbon.\(^1\) Alumina,\(^2\) or carbon dioxide.\(^3\) Rudolph\(^4\) made use of baths of steam (up to 1000°C), naphthalene vapour (200°C), and naphthalene naphthol (30°C).

The heating of the bath is carried out in several ways:

1. By gas jets arranged underneath the test piece, which is held horizontal. This method is adopted by Unwin.\(^5\) for a liquid bath, and by Cachetier\(^6\) for an air bath.

2. By gas jets above a horizontal test piece—adopted by Le Chauffe.\(^7\)

3. By gas jets at the sides. This is used in conjunction with a vertical testing machine by Marles\(^8\) and Bach.\(^9\)

4. Steam-heating coils are used for tests on 60-foot lengths of copper wire, up to temperatures of 60°C, carried out at the National Physical Laboratory.\(^10\)

5. Electric heating coils are used by Strickel\(^11\) and Hopkinson and Rogers.\(^12\)

For general convenience the last method is to be preferred. Two electric furnaces, successfully used at the National Physical Laboratory, are given in Figs. 130 and 132. They are both used in connection with a vertical testing machine.

A platinum furnace for temperatures up to 1200°C is shown in Fig. 130. The heater (a) consists of a platinum strip, 0.07" x 0.0037", wound on a five-hundred cylinder (outside diameter 2-25 inches, thickness 0-137 inch, and 132 inches long), with a pitch of 1 inch. The

---

ends of the strip are clamped in position on the cylinder by metal clips D. A steel case B (about 8 inches diameter and 1/16 inch thick) surrounds the heater, and the space

Sectional Elevation

between the two is packed with asbestos and magnesia fluff. The whole is clamped between two end plates C₁ and C₂, on one of which two insulated terminals are fixed; these are connected to the two ends of the platinum heating coil. The furnace, which is slung from the top shackle of the testing machine, takes a current of 15 amperes.

Fig. 137 shows the 600° C. furnace. With this furnace the heater is formed with nichrome wire wound on to a brass tube A (2½ inches diameter and 15 inches long). The tube is bound with mica, before winding the wire, in order to insulate it, and over the wire a binding of asbestos string is placed so as to keep the former in position when it expands on rise of temperature. The heater is surrounded by a steel case B, 7 inches diameter, and the space between the two is filled with asbestos fluff. Two steel plates C₁ and C₂ are bolted together, clamping the heater and outer case between them, and are arranged to connect the furnace to the frame of the cylinder by metal clips E₁ and E₂. The ends of the heating coil are connected to two insulated terminals on the top plate, No. 18

wire, having a carrying capacity of 1500 °C, is used for the heater.

Uniformity of speed in testing is an important condition for strictly comparable results. As the speed of loading increases larger strength values are obtained. Le Chatelier found that with hard-drawn copper wire tested at 250° C, the ultimate breaking
strength increased from 11.4 to 21.6 tons per square inch as the duration of the test decreased from 1,800 seconds to 20 seconds. Both L.C. Clodeck and Strickland have shown that the elongation of copper diminishes with reduction in the speed of loading.

§ (116) Temperature Measurement for Strength Tests.—With liquid baths sufficient accuracy can usually be obtained by taking the temperature of the liquid, but it is essential that the test should not be carried out until uniformity of temperature is attained.

With an air-bath there is incomplete conduction of the heat between the surrounding air and the test piece, and it is necessary that the temperature of the sample be directly measured. This is most conveniently carried out by means of a thermo-electric pyrometer, which can either be placed in a hole drilled down the test piece, as was done by Brugasky and Spring, \(^1\) or held close against the sample and bound to it with asbestos string.

The thermo-electric pyrometer consists of three distinct parts, viz.: (1) The thermo-couple \(^2\) which receives the temperature. (2) The indicator from which the temperatures are observed. (3) Leads connecting the thermo-couple to the indicator.

The thermo-couple consists of two wires, A and B, of different composition. The ends of A and B are joined together and form a circuit. One junction is placed in a known temperature, usually zero, while the other is placed against the material whose temperature is to be measured. The difference in temperature between these ends sets up an electromotive force which is proportional to the temperature difference. This E.M.F., \(\varepsilon\), is measured and, by means of a calibration, gives the temperature. The cold junction is usually placed in ice in order to ensure a constant temperature.\(^5\)

\(^2\) See "Thermocouples," § (2).

Fig. 130.

thermomax flask is a convenient receptacle for the ice and cold junction.

Various combinations of metals are used for thermo-couples, according to the maximum temperature for which they are to be used:

(a) Base metal thermo-couples.
(b) Iron-constantan (wire) thermo-couples for temperatures up to 600°C. Iron-constantan (cold) thermo-couples for temperatures up to 800°C.
(c) Rare metal couples.

Platinum —

platinum and 10 per cent rhodium for temperatures up to 1400°C.

Platinum —

platinum and 10 per cent iridium for temperatures up to 1400°C.

It is essential for temperatures above 800°C, that the couple should be protected by quartz or porcelain tubes. A thermo-couple placed in small porcelain tubing is seen at \(\varepsilon\) (Fig. 130). The indicator is usually a sensitive moving coil galvanometer of high internal electrical resistance, having the scale marked in temperature readings which depend upon the type of thermo-couple employed. It is generally an advantage to also have the instrument provided with a scale giving its readings in millivolts.
Complete thermo-electric pyrometer outfits are supplied by various firms of instrument-makers. Fig. 128 shows the type of indicator which the author has found most suitable for ordinary high temperature test work. It is supplied by the Cambridge & Paul Instrument Company.

§ 110 Determination of Elastic Limit and Yield Point at High Temperature.

In the majority of high temperature furnaces the test piece is not visible during the test, so that the yield point, if one exists, cannot be obtained by noting the extension by a pair of dividers, and the attachment of an extensometer is more difficult than with tests at air temperature.

In 1890, Martens 1 adapted his mirror extensometer for high temperature work. The test piece \( A \) (Fig. 130 (A)) was turned down in the centre at \( c \). The extensometer clips were attached at \( b \) on the lower enlarged end, and were carried out of the furnace for attachment of the measuring rhombs at \( a \). The extension was therefore measured on the length \( ab \), and correction was made for the extension of the enlarged ends in order to obtain the extension of the gauge length \( ab \).

Rudolff, 2 in 1895, slightly modified Martens' extensometer, in the furnace, the observations are uninfluenced by variations of temperature.

Leo and Crowthor, 3 in 1914, adapted Rudolff's arrangement of clips to a horizontal testing machine; they, however, attached them to the reduced part of the test piece.

In Figs. 130 (C) and 140 is shown the high temperature extensometer which is proving very useful at the National Physical Laboratory.

ELASTIC CONSTANTS

The rhombus are placed between the clips, and the whole is clamped together by a special spring attached to matched on the outer clips.

Extension of the test piece causes relative movement between the clips on and bh, and the distance of the transparent scale, which is measured in the usual way by a telescope or scale. The relative movement of the clips is also measured by two micrometers attached to the inner clips and working against the outer ones.

Curves for tests on phosphor bronze with this instrument are shown in Figs. 141 and 142. Fig. 141 gives the elastic line and limit of proportionality at temperatures of 20, 120, and 286°C, plotted from results with the rhombus and mirrors, and Fig. 142 shows the full stress-strain curves at temperatures of 20, 120, 286, and 386°C, obtained by using the micrometers.

VII. Results of Tests at Varying Temperatures

§ (117) Results of Tensile Tests. (I.) Iron and Carbon Steels.—Strength tests at high temperatures have been carried out since the early part of the nineteenth century.

In 1820 Trenerry and Prinsep-Saint-Briac showed that, although the tensile strength of wrought iron was 370 tons per sq. inch at air temperature, it fell to 6 to 7 tons per sq. inch at red heat. Bulhaine, in 1830, showed that iron possesses a maximum resistance to fracture at 200°C, and this has frequently been verified for iron and steel. It has also been shown that this maximum resistance is preceded by a minimum, which occurs at about 120°C.

An extensive series of tests were carried out on iron and steel at the Watertown Arsenal in 1908, from which the following conclusions can be drawn:

1. The change in the ultimate stress is very small up to about 150°C. There is evidence of a slight reduction at from 100 to 120°C, and after 150°C there is an increase until, at 200°C, a maximum is reached, which is from 10 to 15 per cent higher than the normal. From 200 to 280°C, there is a continuous fall in strength, which at the latter temperature gives a reduction in strength of 80 to 85 per cent of the normal.

2. The elastic limit decreases with increasing temperature. Up to 300°C, this decrease is directly proportional to increase in temperature, so that at 350°C the elastic limit is about 70 to 75 per cent of that at normal temperature.

3. With cast iron the ultimate strength is approximately constant up to 600°C, after which it falls until, at 850°C, it is about 20 per cent of the normal value.

Muir, in 1836, published an elaborate series of tests on the strength of steel at temperatures up to 600°C, and included a determination of the limit of proportionality. He used a paraffin bath for temperatures up to 200°C, a bath of lead and tin for temperatures up to 600°C, and for low temperatures a mixture of three parts by weight of ice and one part of salt. Temperatures up to 400°C were measured with a mercurial thermometer, and for higher temperatures an air thermometer was employed.

Tests by Isaac and Crowther show that the modulus of elasticity of mild steel varies from 20.6-10^6 lbs. per square inch at normal temperature to 12.8-10^6 at 600°C. They also found that the ultimate stress was a maximum at 250°C, but that the stress obtained by dividing the breaking-load by the area at fracture was a minimum at that temperature. The figures given in Table 40 have been taken from the plotted results.

(R.) Alloy Steels.—The behaviour of special alloy steels at high temperature has been studied by Atchinson. A synopsis of results of tensile tests, most of which were made at the National Physical Laboratory, is given in Table 41; these show that the tungsten steels with high percentages of carbon (i.e. about 5-6 per cent) have the greatest tensile strength at high temperatures. This strength is nearly equalled by the high chromium steels also containing a high percentage of carbon.

With high chromium and high tungsten steels the percentage of carbon seems to play an important part in their strength at high temperatures. Thus with the 11 per cent chromium steel, reducing the carbon content from 1-0 to 0-4 per cent reduces the tensile strength at 600°C from 7-5 to 4-8 tons per square inch, while a reduction of the chromium content from 11 per cent to 6-3 per cent, with

1 A. S. A. M. A., 8, 513.
4 Phil. s. d. F. Techn. Versuchsanstalt in Berlin, 1890.
the carbon content at 1 per cent, has no effect on the tensile strength at that temperature.

When the temperature exceeds 600° C, the strength of alloy steels falls off rapidly; this is particularly noticeable with nickel chrome steels and nickel steels, between which there is very little difference at high temperature.

(III) Alloys.—The use of fittings under superheated steam involves temperatures up to 400° C, and the study of brasses, bronzes, etc., up to these temperatures has been undertaken by numerous investigators. Unwin, 1 in 1880, communicated a report to the British Association on tensile tests of delta metal, gunmetal, manganese, copper, brass, a phosphor bronze, and aluminium bronze at temperatures up to 300° C.

Rankine, 2 Bregewyks and Spring, 3 Denison, 4 and Law 5 have also carried out a great deal of work on this subject.

The tensile strength at high temperatures of aluminium copper, aluminium copper munganes, and aluminium zinc alloys are given in the reports of the Alloy Research Committee. 6

The variations, with temperature, in the properties of alloys are fairly regular; there is a fall in the tensile strength as the temperature rises, with change of curvature and sometimes humps in the temperature-ultimate stress curve. Rolled mungane metal, an alloy of 70 per cent nickel with 30 per cent copper, exhibits high strength and ductility at temperatures up to 600° C.

Tests at the National Physical Laboratory 7 is also a slight alteration of the modulus of elasticity with temperatures met with under climatic conditions.

§ (118) TENSILE TESTS AT LOW TEMPERATURES.—These tests are usually carried out by surrounding the test piece with a bath containing a cooling substance, such as:

| Ice for temperatures down to | 5° C |
| Solid carbon dioxide powder for temperatures down to | 50° C |
| Liquid air for temperatures down to | 113° C |

It is essential that the bath should be surrounded with a casing containing down packing or asbestos fluff in order to obtain a uniform temperature.

Rankine, in 1893, found that iron and steel gave increased yield stress and ultimate stress as the temperature was lowered, while the extension was generally decreased by cooling. Tests made at Watertown Arsenal 8 gave an increase of about 60 per cent in the yield stress and 35 per cent in the ultimate stress over the normal values, when tested at -180° C, but the extension decreased by 63 per cent.

Cast aluminium light alloys show an increase over the normal in ultimate strength of 9 per cent at -80° C, and 27 per cent at -180° C.

§ (119) NOTCHED BAR TESTS AT VARYING TEMPERATURES.—Charpy 9 has shown that, with steel, the work absorbed in the fracture of a notched bar test piece rises as the tem-

ELASTIC CONSTANTS

Temperature is increased and reaches a maximum at about 150° C.; it then decreases and passes through a minimum between 400° C. and 500° C., and rises again until red heat is reached.

This work was confirmed by Guillev and Revillon,

placed

who gave the temperatures of maximum and minimum resistence to shock as 200° C. and 475° C. They say that there is no particular fragility in a steel broken at blue heat (300° to 325° C.).

Guillev and Revillon carried out their tests on a Guilley 90 Kg.M. machine (see § 149). The test pieces were heated in an electric furnace to slightly above the temperature required for the test, they were then placed on the anvil and the temperature noted at the time of fracture. The temperature was determined by the use of a thermo-couple inserted in a small hole drilled in the specimen and penetrating up to about 3 mm. from the cross-section to be fractured.

The ends of the test piece were covered with asbestos to prevent the cooling of the extremities when in contact with the anvil. Tests at as close to 100° C. as possible were obtained by heating in boiling water.

Aitken has shown that with alloy steels the notched bar tests at high temperatures are a reflection of the tensile strength of the steels, being more or less inversely proportional to their property. In all cases the steels gave higher values at elevated temperatures than they did under normal conditions.

Results are the average of five tests.

Some tests on carbon steels at low temperatures, carried out at the National Physical Laboratory, are given in Table 42.

Tests at the low temperatures on various alloy steels show that, generally, there is an appreciable drop in the energy absorbed in fracture between 173° C. and -40° C., but that between -40° and -89° C. the drop, if any, is small, and in many cases there is a distinct rise in the value.

per cent reduction of area at fracture of 52, of which the inner or central portion (heartwood) is usually the stronger in mature trees.

The tests were made in a machine of the Wohler type, the test piece running in an oil-bath heated electrically, and show a reduction of 20 per cent in the limiting range of stress by raising the temperature from 20 to 250 °C. They were carried out at a speed of 2000 alternations per minute.

Tests on some rolled aluminium light alloys, by the same method, gave the results in Table 44.

Each annual ring itself consists of two parts, viz. the inner or spring wood and the outer or summer wood, of which the latter is the denser, harder, and stronger. The strength of a piece of timber can therefore be roughly gauged by the proportion of summer wood in the annual rings. The width of the annual rings indicates the rate of growth of the tree—rapid growth being shown by wide rings—they therefore give useful information as to the uniformity of growth. The rings are usually widest at the centre and become closer near to the bark. Their width and distribution often vary in different trees of the same kind, in various parts of the same tree, and in different parts of the same cross-section.

The tests were made in a machine of the Wohler type, the test piece running in an oil-bath heated electrically, and show a reduction of 20 per cent in the limiting range of stress by raising the temperature from 20 to 250 °C. They were carried out at a speed of 2000 alternations per minute.

Tests on some rolled aluminium light alloys, by the same method, gave the results in Table 44.

VII. TESTS ON MATERIALS OF CONSTRUCTION

§ (122) TESTING OF TIMBER.—Examination of the cross-section of a sawn log of structural timber shows a central pith surrounded by concentric rings which are in turn encircled by heartwood. Each ring represents the year in the life of the tree. The roughly divided inner and sapwood,
CONSTANTS

(i.) Density and Specific Gravity.—The density of timber is largely affected by the percentage of moisture that it contains, by its rate of growth, position in the tree, and percentage of summer wood.

As the density is closely related to the mechanical properties of timber, its determination is of importance. It is usually ascertained by measuring and weighing carefully prepared pieces which, for preference, are made in the form of cubes or prisms. If \( b \), \( l \), and \( h \) are the three dimensions of the block in centimeters and \( W \) is the weight in grammes,

then the specific gravity \( = \frac{W}{b \times l \times h} \)

and weight per cubic foot \( = \frac{W}{b \times l \times h} \), where \( g \) is the weight of a cubic foot of water in lbs. (024).

For comparative results the moisture content must be the same; the density is therefore usually carried out on dried samples. For this purpose they are dried in an oven at 100° C. until of constant weight, and the density calculated from this weight in conjunction with the dimensions (dry).

(ii.) Per cent Moisture.—All the mechanical properties of timber are affected by the moisture content. The strength becomes less as the percentage of moisture increases. A determination of the percentage of moisture is always made from each test piece, and results which do not include this factor are valueless.

The determination of the moisture content is made on pieces cut from each sample: In the case of tension, shear, and cleavage tests, these consist of pieces cut off adjacent to the failure. From other pieces a disc or cube is taken from as near to the point of fracture as possible.

Discs, etc., are weighed immediately that they are cut; they are then dried in an oven with free circulation, and kept at a constant temperature of 100° C. until they cease to lose weight by further drying. They are then reweighed. The moisture contained is expressed as a percentage of the dry weight of the timber.

If \( w_1 \) = weight before drying,

\( w_2 \) = weight after drying,

percentage of moisture \( = 100 \times (w_1 - w_2) \div w_2 \).

In order to hasten the drying process, the test pieces are sometimes cut into small matchsticks or shavings bored from the sample used. If this is done, 12 hours' drying is usually sufficient. Drying at 100° C. will eliminate all except about 2 per cent. of the moisture, and this cannot be removed without igniting the sample.

Sections of beams are usually cut into small pieces for a moisture determination of each piece, in order to examine the distribution of moisture throughout the section. The results from such a determination on pieces of spruce and fir are given in Figs. 143 and 144.

(iii.) Rings per inch, per cent of Sapwood, and per cent of Summer Wood.—These estimations

![Figure 143](image)

**Arrangement and number of annual rings**

**Variation of moisture over the section**

Average Moisture = 10.5%

**Fig. 143.**

are usually made on the piece cut for percentage of moisture determination. A line, one inch long, is drawn on the cross-section of the disc

![Figure 144](image)

**Section cut into cubes for moisture determination**

**Variation of moisture over the section**

Average Moisture = 12.0%

**Fig. 144.**

in a radial direction and passing through a region of average development.

The width of summer wood crossed by this line is obtained by spacing off annularly, on a pair of dividers, the width of the summer wood bands for each annual ring in succession. The final distance between the points of the dividers, in hundredths of an inch, is equal to the percentage of summer wood.
The number of rings per inch is obtained by noting the number of annual rings crossed by the measured inch.

The percentage of sapwood is estimated by measuring the amount of the cross-sectional area in which sapwood appears and expressing this as a percentage of the whole area.

§ (123) Drying Timber Test Pieces.—In order to obtain reliable data from the various tests on timber, the information is usually referred to some standard percentage of moisture. It is considered that timber, if thoroughly dried, will retain 12 to 15 per cent of moisture from the atmosphere. Some experimenters therefore use 12 per cent, but the majority adopt 15 per cent as the standard for comparison. Tests are usually carried out at percentages of moisture above, below, and usually left at least ⅓ in. larger on each of the cross-sectional dimensions and also considerably longer. Below drying in the kiln the percentage moisture is obtained from pieces cut from each end of the sample, and from this information the reduction in weight which is required by the kiln drying in order to reduce the sample to the lower moisture content is calculated. The drying of the test sample is continued until the reduction in weight is obtained.

§ (124) Size of Test Pieces for Tests on Timber.—Timber tests are divided into two classes:

1) "Scientific" tests of small specimens free from knots or other blemishes and of uniform moisture content.

2) Tests on full-size members of structures—

approximately at the standard, and for this purpose it is necessary to dry samples from
the higher to the lower figure.

Two methods of drying are adopted, viz.,
air drying (or seasonning) and kiln drying, but
owing to the long time required for successful
air drying, kiln drying is usually resorted to
for test work.

An experimental hot-air-drying oven or kiln,
which has been successfully used, is shown in
Fig. 145. The samples are placed on a tray
A in a circular vessel B which is heated by
a gas burner C, and a current of air is
driven through this vessel by a rotary fan
D. A complete record of the temperature,
which is never allowed to exceed 80° C., is
obtained by a recorder which is placed along-
side the test samples.

The test pieces are prepared from the samples
after drying, and for this purpose the latter are
struts, beams, etc., which are not homogeneous
and contain serious defects.

Tests are necessary under both conditions.
Large sections have the same strength per
unit area as small ones when both are of
the same proportions and similarly free from
defects; but under practical conditions it is
found that this law of similarity is not realized,
and that tests on small pieces give values for
the strength of timber in excess of the strength
of large pieces.

§ (125) Tensile Tests on Timber.—All
comprehensive investigations in regard to the
strength of timber include a determination of
its tensile strength as it is of scientific impor-
tance. The resistance of timber to tensile force
parallel to the grain is greater than under any
other kind of loading. In timber structures the
tension members are joined at their ends in
other parts of the structure, and the weakest
ELASTIC CONSTANTS

point is the joint which is subjected to shear.

It follows that the tensile strength does not
govern the strength of the member, and therefore,
from a practical point of view, it is of
secondary importance.

The heads and shoulders of tensile test
pieces have to be very greatly enlarged,
otherwise failure takes place either by shearing
of the ends along the grain or by crushing of
the ends across the grain. The type of test
piece adopted is shown in Fig. 146. The
section to fracture is naturally small in
comparison to the ends. Test pieces similar to
that shown in the figure, but having the
reduced diameter 1-25 inches instead of 0-501
inches, are sometimes used.

§ (127) SHEARING STRENGTH OF TIMBER.—It
is generally acknowledged by all authorities
that accurate tests of the shearing strength of
timber are difficult to make. Two methods
have been adopted:

(1) With the test piece in double shear as
indicated in Fig. 148.

(2) With the timber under single shear
(Fig. 149). This method has been used with
success by Warren.1

1 "Report of the Department of Forestry N.S.W.,
Australia, 1901," p. N.S.W. Hardwood Timbers."
ELASTIC CONSTANTS

The resistance of various woods to shear across the grain has been determined by Trautwine, whose test pieces were cylindrical pins \( \frac{1}{2} \) in. diameter subjected to double shear.

§ (128) BENDING TESTS.—Bending tests are probably the commonest for timber, because of the great use of wood for rafters, joists, beams, and other parts of structures subjected to bending. Long pieces of fairly large section can be tested without testing machines of big proportions.

Test pieces are usually rectangular, are supported at the ends, and loaded either in the centre or at two points as indicated in Figs. 40 and 41 (§ (12)). The latter method (called four-point loading) is now generally preferred, as the maximum bending moment is spread over half of the span and is not limited to the point directly under the application of the load as it is in the central loading method.

A sketch showing the direction of the grain at the ends, and the number of the annual rings, should accompany each test, as well as an indication of the position and mode of fracture. The position and character of any defects such as knots should also be specially noted. Failure may take place by tension, compression, or longitudinal shear along the grain.

For the determination of the limit of proportionality and coefficient of elasticity it is necessary to measure the deflection for known increments of the load. Instruments for doing this are described in § (50).

The strength factor usually measured is the modulus of rupture or coefficient of bending strength. Although a fictitious value, it is, nevertheless, a valuable index of the quality of the timber.

The various values obtained from the test data are calculated in the following way:

If \( P \) = Total load at the limit of proportionality,
\( b \) = Total load at fracture,
\( l \) = Span between the supports,
\( w \) = Width of cross-section of the test piece,
\( h \) = Depth of the cross-section of the test piece,
\( d \) = Measured deflection at the limit of proportionality.

(i.) For central loading (deflection measured on length \( l \)),
- Greatest shearing stress = \( 3P/4bh \).
- Stress at the proportional limit = \( 3P/2bh^2 \).
- Modulus of rupture = \( 3P/2bh^2 \).
- Modulus of elasticity = \( 3P/2bh^2 \).

(ii.) For four-point loading (where the distance between the loading points = \( L \)), and the deflection is measured on length \( l \), in the section under uniform bending

\[ \frac{1}{2} \]  Frankl. Inst. Journal, cix, 100. moment, and \( I_1 \) is less than \( I_2 \). \( B \) and \( F \) are the sum of the two loads at the loading points.

Greatest shearing stress = \( 3P/4bh \).
- Stress at proportional limit = \( 3P(1-1)/2bL^2 \).
- Modulus of rupture = \( 3P(1-1)/2bL^2 \).
- Modulus of elasticity = \( 3P(1-1)/2bL^2 \).

Fig. 150 shows typical load deflection diagrams for Christiania spruce and Petersburg fir, while Fig. 151 gives the load-extension diagrams in tension and compression for the same materials.
an Impact testing machine (see § (130)) is utilised to carry out this test, and the form of test piece is given in Fig. 153. The test piece is notched with the annular rings as indicated in the sketch, and the top of it, where the tup strikes, is protected by a steel plate.

**Impact Loading Test.**—In this test the specimen (2 x 2 x 30") is supported at the ends on a span of 28 inches. The load is applied by dropping a hammer upon the specimen at mid-span, from an initial height of one inch. For succeeding drops the height is increased by 1-inch increments up to 16 inches, and thereafter drops are made at successive increments of 2 inches, until failure. Hammers of 50, 100, and 250 lbs. are used.

Deflections of the specimen are measured with each drop, and a curve is drawn connecting height of drop and deflection squared. Deflections are obtained from a drop curve traced on a revolving drum.

If \( W \) = weight of the hammer,
\( H \) = height of drop at elastic limit,
\( F \) = fibre stress at elastic limit,
\( D \) = central deflection of specimen at elastic limit,
\( b \) = breadth of specimen,
\( h \) = height of specimen,
\( L \) = span,
then
\[
\text{Fibre stress at elastic limit} = 3WHL/D^2,
\]
\[
\text{Modulus of elasticity} = 12L^2/F/AD,
\]
\[
\text{Work to elastic limit} = WHL/8A,
\]

**§ (130) CLEAVABILITY.**—For the resistance to splitting the U.S.A. Department of Agriculture use the test piece indicated in Fig. 154, and express the results in pounds per inch of width at fracture. Tests have been carried out to determine the resistance to splitting radially as well as tangentially to the annular rings, and the results (Table 46) show that most hardwoods split more easily along radial planes than along tangential surfaces.

Splitting is related to tensile strength across the grain. A high value is advantageous for timber which has to be fastened by nails or spikes.

**§ (131) HARDNESS TESTS ON TIMBER.**—The ball hardness test has been applied to timber in two ways:

1. The first method, adopted by Warren, follows the Brinell test for metals, a ball of fixed diameter is pressed into the timber under a known load stated time. The hardness is calculated from the formula

\[
H = \frac{P}{A^2}
\]

1 Report of the Department of Agriculture, 1911, on "N.W. Hardwood Timbers."
ELASTIC CONSTANTS

where \( E \) = the hardness number,
\( P \) = the load in kilogrammes,
\( A \) = the projected area of the indentation (in\(^2\)).

Warren used a ball of 20 mm, load of 1000 kilos, and time of 2 minutes. He found that the hardness along the fibre is considerably greater than either parallel or perpendicular to the annular rings.

(2) The second method, largely used in the U.S.A., is to press a ball of 0.444 inch diameter into the timber until it has penetrated 0.222 inch. The load required is taken as a measure of the hardness. The test tool is a steel bar with a hemispherical end. This end projects through a hole in the bottom of a cup-shaped washer. When the tool has penetrated the timber to the correct depth there is binding between the steel bar, washer, and specimen. The load at that instant is noted.

With the Ludwik cone test Warren used the standard 90° cone and a pressure of 400 kilogrammes applied for one minute. The depth was measured by an indicator as the test proceeded.

§ (132) RESISTANCE OF TIMBERS TO ABRASION AND WEAK.—Relative wear has been tested by pressing blocks of the material 2 x 2' under a pressure of 26 lbs against a table covered with fine sandpaper and revolving at 68 revolutions per minute. A better method was used by Warren, who utilized a sand-blast. The test piece, 3 x 3 x 1", was clamped against a plate having a 2½-inch hole in it, and together with the plate was rotated about its own axis. A jet of superheated steam under a pressure of 43 lbs per square inch, carrying sand in it, was projected through an expanding nozzle on to the surface of the rotating test piece. The sand-blast wore away the wood on the exposed diameter of 2½ inches, and the loss of weight of the test piece in two minutes' exposure gave a measure of the wearing quality of the wood. Tests were made—

(a) Parallel to the direction of the fibre.
(b) Perpendicular to the direction of the fibre and parallel and perpendicular to the annular rings.
(c) Perpendicular to the direction of the fibre and perpendicular to the annular rings.

The results showed that the wear was least parallel to the direction of the fibre, the ratio in the three directions being \( a : b : c =1:2\frac{1}{2}:4\).

§ (133) HOLDING POWER OF NAILS AND SPIKES IN WOOD.—Nails hold in timber by virtue of the friction developed between the surface of the nail and the fibres of the timber. An investigation into the holding power of nails and spikes in Australian timber was carried out by Warren in 1911, who found that Australian timbers were so hard that it was necessary to first bore a hole slightly smaller than the nail in order to prevent either buckling of the nail or splitting of the timber. Six-inch No. 1 S.W.G. smooth steel wire type nails were driven to a depth of 3½ inches in the timber in holes bored to 2½-inch diameter. They were withdrawn by pulling in the testing machine, and the loads to pull from various depths were noted. The results showed that the holding power was approximately proportional to the depth, as shown in Table 47.

</tbody>
</table>

For driving spikes, holes slightly smaller than the diameter of the spike must be drilled. Warren found that 3-inch square section twisted spikes required 30 per cent more load to withdraw them than 3-inch square or 3-inch circular black iron straight spikes.

Hatt, experimenting with 2-inch square smooth spikes and screwed spikes pitch ¾ inch, root diameter ¾ inch, driven in 1½-inch holes to a depth of 6 inches, found that the plain spikes had about 55 per cent of the resistance of the screwed ones.

Hatt's results agree with those of Warren in showing that the holding power was proportional to the depth.

§ (134) INFLUENCE OF CONDITIONS OF USE UPON RESULTS. (i.) The Effect of Moisture.—The effect of moisture on the strength of wood has been thoroughly investigated by Tammann,
1 and his results, which are fully given by Johnson,
2 show that there is a large increase in crushing strength, modulus of elasticity, and modulus of rupture with a decrease in the moisture content. Table 48 gives the approximate figures for spuce, chestnut, and pine.

(ii.) Effect of Temperature of Testing.—The ordinary variations of temperature of the laboratory (15° C. to 25° C.) are not important, but if greater extremes occur it is advisable that the temperature at which the tests are carried out should be controlled. Tests made at Pennus University show an increase in the strength of red oak lics of from 0 per cent to 17 per cent by testing them at 0° C. instead of 20° C.

3 Materials of Construction, 1918 ed., p. 1095,
(iii.) Effect of Speed of Testing.—Thurston found that 59 per cent of the breaking load given by progressive loading on the ordinary testing machine would break beams if left in place for nine months. Experimenting on the same subject, Johnson determined that it was not safe to assume that the permanent load which timber would carry was greater than 50 per cent of the short time ultimate load as ordinarily found by the testing machine.

It is evident, therefore, that the influence of time must be allowed for in testing wood. As a result of work by Thumann, the U.S.A. Forest Service of Agriculture have standardized fibre strain in testing, e.g.:

The strength of wet or green wood is much more sensitive to changes of speed than in dry wood. A change of the above speeds by 50 per cent may ordinarily be allowed without causing a variation in strength of over 2 per cent.

The modulus of elasticity in bending was found to be practically constant with change of speed.

§ (135)  
**Elasticity of Stone, Brick, and Concrete.**—The important characteristics of stones and bricks from an engineer’s standpoint are ease of working, durability, and strength.

Durability depends on resistance to
(a) Absorption of moisture,
(b) Absorption of water,
(c) Altimut freezing and thawing,
(d) Fire,
(e) Acid.  

Stones and bricks are subjected to pressure to compression, sometimes to transverse stress and shearing, but not to tension except such as would be caused by wind pressure or other lateral forces. Besides resistance to these forces the specific gravity is an important property. For a given stone the specific gravity and strength increase concurrently, while for some purposes greater stability is given by higher specific gravity.

With respect, a knowledge of its elastic constants and tensile strength, of its resistance to fatigue and permeability to water, are requisite for the purposes of design.

(4) Determination of Specific Gravity.—In order to determine the specific gravity (including the pores) the sample is dried at 100° C. until it is of constant weight, and, when cool, coated with a thin film of paraffin wax and weighed in air and water.

If \( W_a \) = weight in air, and \( W_w \) = weight in water, the specific gravity \( \text{SG} = \frac{W_a}{W_w} \).

A correction for the film of paraffin wax can be made if the results are required to a high degree of accuracy.

The true specific gravity of the stone substance is obtained by piercing the dry stone to a powder and determining the specific gravity of the powder with a standardized test cylinder or similar form of specific gravity apparatus.

The porosity of the material can be obtained by making both the above determinations. Then if \( \text{SG} \) = specific gravity of the stone substance, and the other values are as before:

\[
\text{SG} = \frac{W_a}{W_w} \]

Then the porosity \( \text{Porosity} = \left(1 - \frac{W_a}{W_w}\right) \times \text{Porosity of stone} \).  

(5) Absorption of Water.—The usual method of obtaining the amount of water which stone, brick, or concrete will absorb is to immerse the specimen in water at approximately 20° C. after it has been dried at 100° C., cooled, and weighed. The immersion is continued for three days, when the surface water is removed and the material is reweighed. The increase in weight divided by the original weight multiplied by 100 gives the percentage absorption. The process is sometimes hastened by eliminating the long period of soaking and immersing the test piece in water which is slowly raised to boiling-point and kept at that temperature for five hours.

A slight modification is sometimes introduced by weighing the specimen in air \( (W_2) \), in water immediately after immersion \( (W_3) \), and also in water after three days' immersion.
is usually accepted as being the criterion of the mechanical qualities of brittle materials such as stone, brick, and concrete.

In carrying out this test the kind of bonding employed has a great influence on the results. Unwin ¹ has shown that fluidity of the holding produces vertical splitting of the test piece and a considerable reduction of the crushing strength. The common practice of putting wood or lead layers between the test piece and the testing-machine compression blocks, in order to allow for irregularities in the surface of the specimen and to distribute the pressure over that surface, is erroneous. In order to obtain plane parallel faces, Unwin's method of applying thin layers of plaster of Paris has been used by the author for a considerable number of tests without obtaining any unsatisfactory fractures.

The information obtained from the test is the stress at which the first crack appears and the ultimate crushing stress. It is essential that the load should be applied axially, and the compression blocks are usually supplied with spherical seatings (see § 121). From the character of the final breakdown and shape of the fragments it can be determined whether the load was applied correctly.

² Bauscher's Communication, 1891, x. 150.
ELASTIC CONSTANTS

For geometrically similar test pieces, the crushing strength is proportional to the cross-sectional area. Within the limits where bending occurs, the crushing strength becomes less as the height of the test pieces increases. For prisms and cylinders of the same height and cross-sectional area, the crushing strength squared is inversely proportional to the circumference of the test piece.

The compressive strength of concrete is reduced by an excess of water during mixing to a fractional part of that which it would reach under proper conditions (see Table 50).

Representative crushing, bending, and absorption results in stone and brick are given in Table 51.

§130 The Elastic Properties of Stone, Brick, and Concrete.—It has been shown that a linear relation is often not obtained between stress and strain for stone, brick, and concrete (§134), and that for the latter empirical modules are used for the purposes of design calculation.

Professor W. Walker gives the following particulars of the manner in which different variables affect the strength and modulus of elasticity of concrete:

"(a) Both the modulus of elasticity and strength increase within certain limits as the aggregate becomes coarser, although the modulus of elasticity increases less rapidly than the strength.

"(b) An increase in the quantity of cement in the batch causes an increase in values of modulus of elasticity and strength. The modulus of elasticity is affected somewhat less by change in the cement content than the strength.

"(c) The quantity of mixing water exerts a marked effect on the modulus of elasticity and strength. An addition of 25 per cent of water to a mixture of normal consistency decreases the modulus of elasticity about 15 to 20 per cent, and the strength about 35 to 40 per cent.

"(d) Both the modulus of elasticity and strength increase with the age of the concrete so long as the specimens are kept moist during curing. The strength increases in proportion to logarithms of the age. The modulus of elasticity follows approximately the same relation.

"(e) There is no marked difference in the modulus of elasticity and strength of concrete made from high-grade pebbles, crushed limestone, crushed granite, or blast furnace slag.

ELASTIC CONSTANTS

"(f) A comparison of specimens stored 14 days in dump sand and 77 days in air with specimens stored 81 days in dump sand shows that the modulus of elasticity and strength are higher for the dump sand storage.

"(g) Tests for mixing times ranging from 3 to 10 minutes show both the modulus of elasticity and strength to be greater for the longer mixing times."

§ (137) TENSILE STRENGTH OF CONCRETE.—Considerable difficulty is experienced in designing suitable end attachments for tensile tests on concrete. Many experimenters cast spherically headed bolts in the concrete of the ends of the test piece and pull on these heads by the testing-machine grips; others enlarge the ends so as to form the test piece into a flat dumb-bell shape. Particulars of a few dimensions which have been adopted are given in Table 52.

The tensile strength of concrete is about one-eighth to one-twentieth of the crushing strength.

"(h) A comparison of specimens stored 14 clays in dump sand and 77 days in air with specimens stored in damp sand shows that the modulus of elasticity and strength are higher for the damp sand storage.

"(i) Tests for mixing times ranging from 3 to 10 minutes show both the modulus of elasticity and strength to be greater for the longer mixing times."

§ (137) TENSILE STRENGTH OF CONCRETE.—Considerable difficulty is experienced in designing suitable end attachments for tensile tests on concrete. Many experimenters cast spherically headed bolts in the concrete of the ends of the test piece and pull on these heads by the testing-machine grips; others enlarge the ends so as to form the test piece into a flat dumb-bell shape. Particulars of a few dimensions which have been adopted are given in Table 52.

The tensile strength of concrete is about one-eighth to one-twentieth of the crushing strength.

§ Prof., Soc. Eng., Jour., ix, 234.

§ (138) SHEAR STRENGTH OF CONCRETE.—The shear strength of concrete lies between 0.4 and 0.6 of the crushing strength. The shear testing tool is of the same form as that used for metals (§ (123)), but is specially arranged to take a larger test piece. The test pieces are generally cast 6 or 8 inches in diameter and 14 to 18 inches in length, and are tested in either single or double shear.

§ (139) TRANSVERSE STRENGTH OF CONCRETE.—No definite size has been standardised for the strength of puddled concrete when applied for periods not exceeding 30 seconds. If a greater vibration is employed, there is a steady falling-off in strength. After 45 to 60 seconds the strength is only 90 per cent of that given by the standard method of puddling.

If pressure is applied to concrete after

1 University of Wisconsin, Bulletin No. 107.
2 "Effect of Vibration, Jugging, and Pressure on Fresh Concrete" Structural Materials Research Laboratory, Chicago, 1915, Bulletin No. 8.,
ELASTIC CONSTANTS

moulding, water is expelled and a drier concrete is produced. This gives increased strength.

Amounts: that a pressure of from 200 to 500 lbs. per sq. in. during moulding increases the compressive strength by 20 to 35 per cent.

§ (142) PERMEABILITY OF CONCRETE AND MORTAR.—Permeability depends upon minute passage ways in the material which are so connected that water can flow right through. Tests under high heads of water have been made, and show that even cement paste is not absolutely imperious. Concrete and mortar can, nevertheless, be made which, under normal pressures, do not allow any dampness on the outside.

Two methods of test are employed:

1. The amount of water passing through the material is collected and weighed.

2. The weight of water, which has to be supplied in order to keep a constant head, is measured (i.e. the water going into the test piece).

The arrangement of a suitable apparatus for Method 1 is given in Fig. 156, and a section of the test piece, together with the can for catching the water, in Fig. 157.

The test piece (7\(\frac{1}{2}\) inches diameter) has annular spaces at the outer edges of both the top and bottom surfaces painted with a rubber waterproofing paint. This leaves an annular place 5 inches diameter in the original condition. Rubber washers A, A are placed over the waterproofing, and the specimen is securely clamped between the two cast-iron plates P, P.

The water is applied to the top of the test piece through the pipe C, and any water passing through is caught in the can B. The specimen is soaked in water for 48 hours immediately before the test.

The arrangement (Fig. 156) permits of six tests being carried out at once. Each test piece with its holder is attached to a union C. The water passes through a filter D and tank E before reaching the specimen. Air pressure is supplied to the tank E by a compressor, an air reservoir F being inserted to equalise the pressure. Three gauges G are provided for reading the pressure—two on the air reservoir and two on the water pipe. Readings of the water collected in the can A are taken at frequent intervals at the commencement of the test; but the rate of percolation of water diminishes as the test proceeds, and the intervals between the readings can be reduced until it becomes constant.

In order to measure the water supplied (Method 2), the arrangement is slightly modified by fitting a water reservoir K above the test pieces holder (Fig. 158). This reservoir is only partly full of water, and the pressure is applied to the top of the water by

![Diagram](image-url)
ELASTIC CONSTANTS

With an investigation carried out at the N.P.L. on the permeability of reinforced concrete under a pressure of 8-7 lbs. per square inch, air pressure was replaced by an actual head of water of 20 feet, which was kept constant by adding water to a reservoir as described for the last experiment.

§ (143) TESTING ROAD MATERIALS.—There are two methods of estimating the comparative value of materials for road construction. The first is to lay sections of a road with the materials which are to be compared and observe the effect of traffic on them, and the second is to subject the road materials to laboratory tests designed to imitate actual conditions met with on the road. The former method, with great care, will give results, but the process is long and costly. The use of some form of experimental road sections is, however, the only thorough method of testing asphalt carps. Observations of the behaviour of macadam roads, constructed with rocks whose physical characteristics have been determined by laboratory tests, enables these tests to be used in order to judge the probable adaptability of any rock for use in road construction.

A determination of the relative road-building qualities of different types of rock was first systematically attempted in France. The French School of Bridges and Roads installed a road materials laboratory in 1878, and it was there that the Deval Attrition Machine was designed, and its excellence has led to its general adoption as a standard testing machine.

The testing of road metal was initiated in Germany in 1881 at the first Finnish Conference for Establishing Uniform Conditions of Testing. They appointed a committee to draft the methods of testing that were necessary, the work performed by this committee was reported to conferences held in 1886, 1890, and 1893, and definite proposals for testing, including the Deval test, were submitted and approved.

In 1893 Massachusetts Highway Commission founded a laboratory for testing road materials in the Lawrence Scientific School of Harvard University. In 1900 the United States Government, because of the growing importance of road-material investigations, established a laboratory in the Bureau of Chemistry of the Department of Agriculture. This laboratory, transferred in 1905 to the Office of Public Roads, examines, without charge, samples of road material submitted by any citizen of the United States.

The only stone-testing appliance founded to be in existence in England prior to 1911 was the “Rattle” attrition machine, designed and used by F. J. Lovgrove,2 Borough Engineer and Surveyor of Hornsey.

In 1911 a road laboratory was inaugurated as a division of the Engineering Department of the N.P.L., Teddington, in accordance with a scheme drawn up by the Road Board and approved by the Treasury. The work of the Road Board has now been taken over by the Ministry of Transport (Roads Department).

In order to preserve continuity with the work which has been in progress in other countries, standard types of machines, as used by the United States Office of Public Roads, were adopted.

§ (144) Attrition Test.—The machine used for this test is of the four-cylinder Deval type, which has given satisfactory results in France since 1878. It is shown in Fig. 150, and consists essentially of four cylinders, 71/2 in. in diameter and 14 in. long, mounted on

Fig. 150.

4 Ann. des ponts et chaussées, 1878, and Bulletin du Ministère des Travaux publics, 1891.

2 Lovgrove, Pitt, and Howe, Handbook of Stones, Attrition Tests in the Light of Petrology.
a frame in such a way that their axes are inclined at 30° to the axis of rotation.

Eleven pounds of rock, numbering as nearly fifty pieces as possible, are placed in one of the cylinders, the cover bolted on, and the machine revolved 10,000 times at a rate of about 30 revolutions per minute. The dimensions of the stones should be such that every stone will pass through a 23-in. ring but will fail to pass through a 2-in. ring. Only the material worn off which will pass a sieve of 5-in. mesh is considered in determining the amount of wear. This amount is expressed as a percentage of the 11 lbs. used.

In addition the French coefficient which is in general use is calculated. This is defined by the relation

French coefficient of wear = \frac{40}{\text{Percentage of wear}}

A wet test is also made, and for this purpose 1-l. gallon of water is placed with the 11 lbs. of stone. With the majority of stones it is found that there is more wear under a wet test than under the dry test, but occasionally the reverse is the case.

An approximate relation has been established between this machine and Lovegrove's Hornsey Rotator.

§ (145) REPEATED BLOW IMPACT (TOUGHNESS TEST). (1) Preparation of Specimen.—The specimen is prepared in the form of a cylindrical cylinder 1 in. diameter by 1 in. long. A piece of the rock is roughly chiseled into size 1\(\frac{1}{2}\)" x 1\(\frac{1}{2}\)" x 3". It is ground approximately cylindrical on a large cradle wheel, and then placed in the chuck of a grinding machine, where it is ground by a small cradle wheel to exactly 1 in. in diameter. The chuck and stone are then taken to the diamond saw (Fig. 109), where the specimen is cut off 1 in. in length.

(ii.) The Testing Machine.—The machine used for this test is known as the Page Impact Machine (Fig. 101). The blow is given by a 4-lb. hammer II, and acts through a plunger P whose surface of contact with the specimen is spherical, and has a radius of 0.4 in.

The blow, as thus delivered, approximates to the blows of traffic, and the spherical end has the further advantage of not requiring great exactness in getting the two bearing surfaces of the test piece parallel; the entire load is applied at one point, on the upper surface. The test consists of a 0.4 in. fall of the hammer for the first blow, and an increased fall of 0.4 in. for each succeeding blow, until failure of the specimen occurs. The number of blows required to destroy the test piece is used to represent the toughness.

A sprocket chain S driven from the shafting is supported on sprocket wheels attached to castings at the top and near in the base of the machine. The chain is provided with small hooks which engage a spring bolt attachment projecting inwards from the top of the hammer. This raises the hammer until it is tripped by a rod R projecting downwards from a crosshead which slides on two rods connecting.
the upper and lower castings. The cross-head is raised automatically through 0-4 in. after every blow by a lead screw driven by a worm and worm-wheel attached to the same shaft as the upper sprocket wheel. By throwing the lead screw out of gear with the crosshead the latter can be raised or lowered through any desired height or the test can be made with a constant height of fall.

A slightly different method of preparing the test sample is sometimes employed, viz. by the use of a core drill. This consists of a brass core tube having at its lower end a steel ring containing eight small diamonds in its cutting edge, four on the outer edge, and four on the inner edge. The drill arranged to cut a core 1 in. diameter runs at 200 to 300 revolutions per minute. Water is supplied to the inside of the drill and the specimen, through a stationary brass ring by a rubber tube connection.

§ (140) Abrasion Test.—The specimen is prepared in the same manner as that for the repeated blow impact test, and in cases where both tests are required the specimen can usually be both cut from the same sample.

The machine used (sometimes called a Hardness Machine) is of the "Darryl" type (Fig. 162), and consists of a circular cast steel disc D which revolves in a horizontal plane about a vertical shaft. The specimen S is held with its axis vertical and its lower end pressed with a force of 3-6 lbs. per square inch against the surface of the disc. Standard sand, 30 to 40 mesh, is fed continuously upon the disc through funnels F, and it is important that an even and constant supply of the abrasive material should be fed to each sample tested. After 1000 revolutions of the grinding disc, revolving at the rate of about 25 revolutions per minute, the loss of weight of the specimen is found. The test is repeated with the specimen reversed, and the average loss of weight computed from the two runs is used in determining the hardness.

This is given by $H = 1000 - \frac{W}{x}$, where $H$ is the hardness number or coefficient of wear and $W$ is the loss in grammes per 1000 revolutions.

§ (147) Cementation Test.—The cementation value of a rock dust measures the ability of that dust to hold the individual particles together to form a firm impermeable road surface.

The processes involved in making a test of the cementation value of a rock are as follows:

(i.) Grinding up a mixture of the rock, coarsely crushed, and water into a stiff paste in a ball mill.

(ii.) Forming briquettes from this paste in a mould under pressure, which are dried after 24 hours.

(iii.) Subjecting each briquette to repeated blows with a small hammer, and measuring automatically the recoil of the hammer after each blow.

(i.) Ball Mill (Fig. 163).—1-lb. of crushed rock and 0-02 gallon of water are placed in the mill together with three steel shots each 5 in. in diameter. The samples are ground in this mill for 2 hours, the mill revolving at the rate of 2000 revolutions per hour. The resulting paste is then ready to be moulded into briquettes.

(ii.) Briquette Machine (Fig. 164).—The paste is placed in a mould M and a cylindrical plug P screwed upon it. The mould is in contact with the short arm of a weighted beam $W$, so that the pressure can be regulated to give a maximum value of 1880 lbs. per square inch. The size of the briquette is 1 in. diameter and 1 in. long.

(iii.) Repeated Impact Machine (Fig. 165).—After drying for 20 hours in air and 4 hours in a hot-air bath at 209° F., the briquette is allowed to cool for twenty minutes in a desiccator; it is then placed on the anvils of
from each sample, and the average result is taken as a measure of the cementing value of the material.

Table 15 gives the interpretation of the results from the physical tests on road stones.

§ (118) Petrological and Geological Characteristics.—Thin sections are cut from the stone and examined under the microscope to ascertain the nature, quantity, and diminution of the component which form the stone and determine the correct petrological designation of the material.

§ (140) Fuhrman Tests.—Specific gravity, absorption of water, crushing, sand-blasting absorption, and paving-brick milling tests are carried out in the manner previously described for stones, bricks, and cements in § (135). It is usual, however, when dealing with road stones, to make the crushing tests on cylinders 1 in. or 2 in. diameter with the length equal to the diameter. The crushing test pieces, when 1 in. diameter, are identical with those for impact and abrasion tests, and can be made with the same apparatus.

§ (150) Endurance Tests on Model Roads.

—It was recognised that in the case of the various test road trials laid down in this country, such as those at Shiphay, the best method of road construction would not show measurable wear or deformation until after years of heavy traffic. At the suggestion of Col. Crompton, Consulting Engineer to the Road Board, a model road-testing machine was designed at the National Physical Laboratory in order to provide a more rapid method of comparing the efficiency of methods of construction.

</table>

This design was approved by the Road Board and its construction was commenced in 1912, the first run taking place in 1913. The machine (Fig. 105) consists of a circular track, 30 in. wide, having a mean diameter of 34 feet. The endurance of the centre 24 in. of this track is tested by the rolling on it of eight steel-tyred wheels, 3 in. wide and 39 in. diameter. The wheels are at an angular distance of 45° from each other, and each wheel is rotated by a separate electric motor mounted on a steel arm which
ELASTIC CONSTANTS

...round a centre post. The radial distribution of the wheels is such that the whole width of 24 in. is covered in one revolution of the arms, and in order to prevent,

(i.) By excessive wave formation,
(ii.) By disintegration,
(iii.) By a combination of disintegration and excessive wave formation.

as far as possible, the formation of ruts in the tested surface each wheel is moved backwards and forwards radially by a cam mechanism through a distance of 1 in. The eight arms are all hinged to a rotating boss on the centre post, and at their outer ends are connected by spiral springs to eight corresponding cantilevers rigidly fixed to a second rotating boss connected with the former and immediately below it. The pressure of each wheel on the track can be adjusted to any desired value up to one ton.

In order to investigate the question of the formation of waves a special apparatus (Fig. 167) has been constructed for drawing cross-sections of the road at different points round the track and longitudinal sections at the centre of the tracks of the eight rotating test wheels. Plaster casts are also taken to obtain a permanent record of the appearance of the road at various stages during the test.

It has been found that a road becomes too bad for use in three ways:

The formation of waves is increased by the road being subjected to heavy traffic after insufficient or unequal consolidation, while disintegration occurs rapidly with change of climatic conditions, if the road consists partly

of small or large stones, when these stones are brought to the surface by deformation or wear.

A summary of the more important tests carried out with this apparatus is given in the Sixth Annual Report of the Road Board (1910).
ELASTIC CONSTANTS

§ (151) BITUMINOUS MATERIALS.—The physical character of bituminous binders and aggregates is determined by microsections, pycnometer and viscometer determinations, quantity and quality of the contained bitumen (whether natural or artificial), and the physical and chemical examination of the residue.

§ (152) LIMES AND CEMENTS.—The cementing materials ordinarily used in engineering construction are classified as follows:

(1) Gypsum plasters.
(2) Limes—quicklime, hydrated lime, hydraulic lime.

§ (153) GYPSUM PLASTERS.—In plaster of Paris, Keene’s cement, stucco, etc., the essential constituent is gypsum in a more or less dehydrated state.

Gypsum in its native state is crushed and ground, and then calcined at a temperature of 200° C. The product is then finely ground and screened.

Plaster of Paris is produced when the gypsum is not completely dehydrated. The theoretical composition of gypsum is CaSO₄·2H₂O (a hydrous calcium sulphate). Plaster of Paris has the approximate composition of CaSO₄·0.5H₂O. The specific gravity of gypsum is 2.3, of plaster of Paris 2.65, and of completely dehydrated gypsum 2.95.

Keene’s cement is practically pure calcium sulphate with a small percentage of calcium carbonate (CaCO₃). For the manufacture of this cement the gypsum is passed in as pure a state as possible, and the resulting product is of an exceptionally pure white colour. The small percentage of CaCO₃ is introduced by dipping the calcined gypsum into a solution of lime and then burning again. The introduction of this “impurity” produces a slow setting cement which ultimately becomes very hard.

Cement plaster and stucco are calcium sulphates with admixtures which retard setting and increase plasticity.

§ (154) LIMES.—Pura lime (quicklime) is produced by the calcination of nearly pure limestone, at a temperature of about 500° C., in some form of vertical kiln. By this process the carbon dioxide is driven off from the calcium carbonate (CaCO₃→CaO). Such limes also violently on the addition of water, form calcium hydroxide (Ca(OH)₂), and increase in volume by about 300 per cent. They harden slowly by absorbing carbon dioxide from the air.

Pure limes have a high percentage of magnesia and shake more slowly.

Owing to the fact that quicklime is insufficiently slackened or mixed in many cases when this is done on the job, this process is sometimes carried out in especially designed and equipped plant, where the operations are conducted more efficiently and with the minimum quantity of water. The resulting product is thoroughly screened and ground and is known as hydrated lime.

Pure hydrated lime should have a specific gravity of 2.04. It is usually tested, by chemical analysis, for fineness and soundness, and sometimes for tensile or compressive strength, in the manner presently to be described for Portland cement.

Hydraulic Lime.—John Smeaton discovered that limesone containing a small percentage of clay, when calcined, produces a lime which hardens by chemical action apart from the absorption of carbon dioxide from the air. This lime sets in the usual way, and, in addition, hardens under water; it is therefore called hydraulic lime.

§ (155) HYDRAULIC CEMENTS, of which the best example is Portland cement, are produced by the calculation of chalk and clay or suitable limes and slakes.

In various parts of the world there are deposits in which the mixing of these materials has been carried out by nature. The result of calculation of these natural deposits produces a natural hydraulic cement. The natural rock contains as a rule an excess of carbonates of lime, rendering the resulting cement poor in quality.

Portland cement is an artificially produced cement in which the chalk and clay are accurately proportioned and thoroughly mixed together, before burning to a hard clinker at a temperature of about 750-800° C. The clinker is then ground, and forms the final Portland cement. A finely ground cement makes a stronger mortar than a coarsely ground one, hence the fineness of the cement is a property which it is necessary to specify.

Portland cement is a British invention. It was discovered by Joseph Aspin in 1824, and it owes its name to its resemblance, when set hard, to Portland stone. It sets rapidly, sets under water, and hardens slowly with little change in volume, and is nearly as strong as stone. The hydraulic property is due to the presence of silicate of alumina.

The British Engineering Standards Association, in their standard specification, define Portland cement as follows: “The cement shall be manufactured by intimately mixing together calcareous and argillaceous materials, burning them at a clinker temperature and grinding the resulting clinker.”

Cementing materials are subject to large variations in the quality. It is necessary therefore to closely control the manufacture by imposing tests to ensure that the proportions which it has been found are of first importance should reach a specified standard.

The main properties required in a cement
are strength, permanence, and time of setting suitable to the work.

The principal tests which are in general use to determine the suitability of the cement for fulfilling those requirements are:

(a) Fineness of grinding.
(b) Specific gravity. (This test was deleted.

Both the B.E.S.A. and A.S.T.M. that the wire mesh of the sieve (not twilled), and that the mesh mounted in frames with sizes adopted are slightly two specifications. Particulars.

from the B.E.S.A. specification in August 1920.

(c) Chemical composition.
(d) Strength.
(e) Time of set.
(f) Soundness or constancy of volume.

In order to obtain uniformity in the testing results, it is necessary that the conditions of test should be exactly the same in each case; and that the personal element should be, as far as possible, eliminated.

This has been provided for in the various specifications for Portland cement, such as those by the British Engineering Standards Association (B.E.S.A.) or the American Society of Testing Materials (A.S.T.M.), in which standard methods for carrying out the tests are described in detail.

(5) Sampling.—It is important that (1) the sample is representative of the whole consignment; (2) a sufficiently large sample is secured to carry out, in duplicate, all the tests required; (3) the sample of the sample is such that the quality of the cement is not affected before the tests are made, and (4) the sample is properly mixed if it is obtained from various parts of the consignment.

Eight pounds of cement are usually sufficient for a sample. The B.E.S.A. specify that each sample shall consist of equal portions selected from twelve different positions in the bags, hogs, or barrels. Samples are usually stored in air-tight tins.

(ii.) Fineness Tests.—The fineness of cement for specification purposes is determined by means of the weight of residue (as a percentage of the original weight of the sample) which is left on a sieve after a definite period of sifting.

Mechanical shaking is done in laboratories where a large mass is to be carried out. The material, as very little time is allowed to the cement, is obtained by the use of very fine air or a very fine powder, air or a very fine powder, air or a very fine powder, air or a very fine Effect of Fineness of Cement on Concrete.
The specific gravity of cement is lowered by adulteration, hydration, or under-burning. The differences in the specific gravity are usually so small that it is necessary to exercise great care in making the determination.

The specific gravity of cement should not be less than 3.10. The method of determination which is recommended is by means of a specific gravity bottle. The standard Le Chatelier apparatus is especially designed for use with cement. It is a volumenometer in which the liquid used is benzine, petroleum, or paraffin which has been freed from water by standing over quicklime (water causes hydration of the cement and therefore an alteration of volume).

(iv) Chemical Composition. The chemical analysis is not so important as the physical tests on cement. It, however, gives valuable indications in the detection of adulteration with considerable amounts of inert material, such as slag or ground limestone. It is also used to determine whether magnesia and sulphuric anhydride are present in excessive quantities.

(v) Strength Tests. A finely ground cement will take a certain amount of inert material without reduction of strength, whereas, a coarsely ground cement will give a high strength as a finely ground one when the test pieces are made with neat cement. As cement is seldom used neat, a strength test on the neat material is an indication of its strength when used in practice; it, however, gives information regarding the time of setting and the soundness. Tests on briquettes made with cement and sand (usually 1:3 by weight) are consequently specified, as a rule, in addition to those on neat cement.

Cement is never used in tension, yet tensile tests are generally carried out in order to give an indication of strength. This is chiefly on account of their simplicity, rapidity, and cheapness. There is, however, a tendency in some countries for compression tests to be substituted for the bighere universally adopted tensile method. It is to be noted that the recent strength tests by Abrams on fineness of cement, already referred to, were made on concrete test pieces in compression.

§ (160) Tensile Strength of Cement and Mortar. Test pieces used for tensile tests are moulded into the form shown in Fig. 108, which represents the briquette standardized by the B. E. S. A. The differences between this and the A. S. T. M. standard are only slight.

The form of briquette has a considerable influence on the results. Color 1 found that the ratio of the maximum stress to the mean stress with the B. E. S. A. briquette is 1.75 approximately, while the American and Canadian forms give a value of 1.70 and 1.05 respectively. The intensity of stress is greatest along the sides of the minimum section and least at the centre.

Either single or gang moulds (see Fig. 109) are used for preparing the test pieces. The former permits a number of briquettes to be moulded at one time and are preferred by many laboratories, since the greater quantity of material that can be mixed tends to produce more uniform results.

(1) Neat Cement Tensile Tests. The quantity of water used in gauging has a considerable influence on the strength of the briquette, and should be such that the mixture is plastic when filled into the moulds. The amount of water varies with different cements, and it is usual to make trial experiments to find the exact amount of water that is necessary. This varies from 18 to 25 per cent by weight of the cement.

The moulds, during filling, rest on slate or some form of non-porous plates. They are filled by using a blade of an ordinary 7½ oz. gauging trowel, and it is usual to specify that no ramming or tamping is permitted. The temperature of the room and of the mixing water should be as near to 18°C as it is practicable to maintain it.

The briquettes are kept in their moulds, in
To improve the method of testing the briquettes, a damped atmosphere is used in a small testing machine. The briquettes are hung in a damp chamber, and the load is applied through a plunger, which is automatically removed when the briquette breaks. The load is applied and removed in a steady and definite rate.

The concrete and sand are mixed in the proportion of 1:3 by weight. The cement is made into briquettes, which are hung in a damp chamber. A load is applied to the briquette, and the load is automatically removed when the briquette breaks. The load is applied and removed in a steady and definite rate.
ELASTIC CONSTANTS

a room temperature and water temperature of 10° C.

The method of filling is described by the B.E.S.A. specification as follows:

"The mixture ganged as above shall be evenly distributed in moulds of the form required, each mould resting upon a non-porous plate. After filling a mould a small heap of the mixture shall be placed upon that in the mould and patted down with the standard spatula until the mixture is level with the top of the mould. This last operation shall be repeated a second time and the mixture patted down until water appears on the surface; the flat only of the standard spatula is to be used, and no other instrument or apparatus is to be employed for this operation. The mould after being filled may be shaken to the extent necessary for expelling the air. No ramming or hammering in any form will be permitted during the preparation of the briquettes, which shall then be finished off in the moulds by smoothening the surface with the blade of a trowel." The standard spatula is shown in Fig. 171.

Various types of modelling and mixing machines have been devised and are in use in some countries. They are, however, not allowed by the B.E.S.A. specification. Mechanically moulded briquettes give greater strength than hand-moulded ones.

Mortar briquettes are stored in moist air for twenty-four hours and then in water (at 10° C) until required for testing. They should be broken as soon as possible after being taken out of the water, and should never be allowed to dry. The B.E.S.A. specify that six briquettes are broken after periods of seven and twenty-eight days respectively, at a uniform rate of boiling of 300 lbs. per minute (400 lbs. per minute in the U.S.A.). The strength should not be less than 200 lbs. per square inch at seven days after gauging, or x-40,000/lb. per square inch twenty-eight days after gauging, where x= the actual strength at seven days in pounds per square inch.

§ (157) Characteristic Equations for Tensile Tests.—Unwin has found that the rate of hardening of cement and cement and sand briquettes follows, very approximately, a simple law.

If y = the strength of the briquette in pounds per square inch at x weeks after gauging, and a, b, and n are empirical constants, Unwin found that

\[ y = a + bx^n \]

n is constant for one cement, and if a be taken as the initial strength after one week,

\[ y = a + bx \]

For tension briquettes the gain of strength is nearly proportional to the cube root of the time of hardening.

Thus for Portland cement in tension \( n = \frac{1}{3} \)

and

\[ y = a + b(x - 1)^{\frac{1}{3}} \]

where \( a = \) the initial strength (at 7 days),

\( b = \) a constant varying with the rate of increase with time.

These two constants give a clear indication of the character of the cement.

In the B.E.S.A. specification for Portland cement briquettes, the lowest value which is accepted for \( a \) is 450 lbs./sq. in., and the minimum value for \( y \) is therefore 450 + 40,000/450 = 530,

and if \( x = 1 \),

\[ 530 = 450 + b \frac{1}{3} \]

therefore \( b = 61.8 \),

or \( y = 450 + 61.8 \frac{x}{3} \).

§ (158) Setting Time.—There is a distinction between setting and hardening. The initial setting is the commencement of the chemical action which occurs when the water combines with the cement; hardening is a much slower process. As a disturbance of the setting process may produce a loss of strength, it is desirable that the initial setting is not interrupted, and that the whole operation of mixing and moulding should be completed before the cement begins to set.

The initial setting time is the time which elapses from the moment water is added until the paste ceases to be fluid and plastic. For the B.E.S.A. specification the time is taken from the moment that the special mould is filled with the gauged cement, and not from the time that water is added to the cement.

The final set is required when the material attains a certain degree of hardness.

The B.E.S.A. specification of March 1915 recognised three distinct gradations of time of setting, viz.:

<table>
<thead>
<tr>
<th>Grade</th>
<th>Initial Setting Time in Minutes</th>
<th>Final Setting Time in Minutes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Quick</td>
<td>Not less than 2</td>
<td>10 to 20</td>
</tr>
<tr>
<td>Medium</td>
<td>Not less than 10</td>
<td>20 to 30</td>
</tr>
<tr>
<td>Slow</td>
<td>Not less than 30</td>
<td>30 to 60</td>
</tr>
</tbody>
</table>

In the revised specification (August 1929), the medium and slow setting cements are replaced by a grade having a minimum initial setting time of 20 minutes and a maximum
The final setting time of 10 hours. The quick setting grade is retained, but the minimum final setting time is not now specified— the maximum final setting time is not to be greater than 30 minutes.

The test block for setting time is made in a special mould (80 mm. diameter and 40 mm. high) filled with neat cement, mixed and gauged in the manner described for tensile tests.

The time of initial setting is determined empirically by the time taken, after filling the mould, for a weighted needle to cause to pierce the test block completely. The B.E.S.A. specification has decided on a special apparatus for carrying out this test called the "Vinet" needle. The needle is one millimetre square in section with a flat end, and the total weight of needle and attachments is 300 grammes. The apparatus is fitted with a device for measuring the depth of penetration of the needle.

The final setting time is determined empirically by the same apparatus, but using a slightly different form of needle. A needle of the same section as before projects 0·5 mm. beyond a hollowed-out circular cutting edge (5 mm. in diameter). The final setting time is taken as that when the needle makes an impression but the circular attachment fails to do so.

The setting times are affected by the temperature of the mixing water, the percentage of water used, and the temperature and humidity of the air. It is preferable for the tests to be conducted in moist air.

§ (159) SOUNDNESS OR CONSTANCY OF VOLUME.—A cement which remains perfectly sound is said to be of constant volume.

Failure is shown by cracking, swelling, blowing, or disintegration. To ascertain the soundness of Portland cement a rough test is to make a pat of cement ⅛ inch thick, gauged with 25 per cent by weight of clean water on non-porous material, preferably glass. This is placed in water at 10° C., after twenty-four hours in moist air, and left there for inspection at intervals; it should show no signs of failure.

This test is sometimes accelerated by exposing a pat of the cement for five hours, in an atmosphere of steam, at a temperature of 98° C. to 100° C.

The test specified by the B.E.S.A. is the Le Chatelier test. This is made in the apparatus shown in Fig. 172, which consists of a small split cylinder of brass (0·5 mm. thick) forming a mould 30 mm. internal diameter and 30 mm. high. On either side of the split two indicators with pointed ends are attached. The distance from the centre of the indicators to the centre of the cylinder is 105 mm.

The Le Chatelier test has been accepted unreservedly in England, and the International Association of Testing Materials decided to recommend the method as the standard accelerated test for constancy of volume of cements. The method is to be carried out as follows:

"The cement is gauged and filled into the mould on a plate of glass, the edges of the mould being held together. When the mould has been filled it is covered with a plate of glass held down by a small weight, and the whole is immersed in water at 15° C. for twenty-four hours. Any tie or band which has been used to keep the edges of the mould together during setting time is then removed. The distance between the indicator needles is then measured and the mould is placed in cold water, which is raised to a temperature of 100° C. in the course of half an hour and is kept boiling for six hours. The mould is removed from the water, and after it has cooled the distance between the indicator needles is again measured. The difference between the two measurements represents the expansion of the cement. This must not exceed ten millimetres when the cement has been stored for twenty-four hours, and five millimetres when the cement has been stored for seven days."

§ (100) EFFECT OF STORAGE ON CONSTANCY OF STRENGTH OF CONCRETE.—Ahmone 2 finds that the effect of storage of cement on the strength of concrete or mortar is largely a question of the age at which concrete or mortar is tested. The storage period and the age of the concrete or mortar at test are of greater importance than the exact condition of storage, so long as the cement is protected from direct contact with moisture. The deterioration of cement in storage appears to be due to absorption of atmospheric moisture, causing a partial hydration, which exhibits itself in reducing the early strength of the concrete and prolonging the time of setting.

Compression tests of concrete and mortar show a deterioration in strength with storage of cement for all samples, for all conditions and periods of storage, and at all test ages.

ELASTIC CONSTANTS OF METALS—ELASTICITY, THEORY OF

ELASTICITY, THEORY OF

§ (1) INTRODUCTION.—The theory of elasticity is concerned with the small relative displacements of different points in a body which occur under the action of applied forces. These forces may or may not constitute an equilibrating system, but in the great majority of examples which have been treated hitherto they are both in equilibrium and steady, so that ultimately the problem is one of the statics of such composite particles. Logically considered, the science follows that of rigid dynamics in the process of development by which the scope of mathematical analysis has been extended to encompass more and more of the properties of real bodies. Thus, the theory of the "dynamics of a particle" treats of motion in its simplest form, and can be applied to problems in which it is sufficiently accurate to assume that the displacement of every particle is the same. Rigid dynamics takes account of the additional complexity introduced by rotation, whereby the motion of a constituent particle depends upon its position in the body; but it retains the assumption that the distance between any two particles is unchanging, and is thus equally powerless to deal with such problems relating to the behaviour of real bodies (in which absolute rigidity is never experienced) as the determination of the pressures with which a heavy beam will bear upon three or more supports. It is left for the theory of elasticity to bring problems of this nature, for the first time, within the range of exact calculation.

§ (2) ELASTICITY DEFINED.—Practically all materials which are employed in construction exhibit to some degree the property of elasticity; that is to say, they deform under the action of applied forces, but when the forces are removed they recover their original shape. In the theory of elasticity, as at present developed, this property is regarded as absolute, and the applicability of its results to practice is limited in the main by the extent to which actual materials may be considered to satisfy its fundamental assumption—that their behaviour under applied forces is independent of their previous history. It is doubtful whether perfect elasticity, as thus defined, is exhibited by any actual material. Thus, the behaviour of wood under applied forces is dependent to a considerable extent upon its dryness and temperature, and of rubber upon the forces to which it has recently been subjected; most metals and other crystalline materials possess practically perfect elasticity under small forces, but their behaviour depends in part upon their previous history when the forces exceed certain limits.

§ (3) STRESS AND STRAIN.—In the development of the precise mathematical theory it is found convenient to introduce two new physical concepts, for which we employ the terms "stress" and "strain." To understand these terms, we may consider the motion or equilibrium of that portion of an elastic solid which is contained within the volume of the small parallelepiped indicated in Fig. 1. The contained material will in all practical instances be subjected to body forces such as gravity, and to balance these (and also to overcome its inertia, if the material is in accelerated motion), forces must be exerted across the containing faces by the surrounding material. We need not concern ourselves here with the difficult physical problem of explaining the mechanism by which these forces are exerted; it is sufficient for our purpose to remark that the action, whatever it is, must be of a reciprocal nature; that is to say, the force which is exerted upon the contained material, across the face ABD', by the surrounding material must be equal and opposite to the forces which is exerted by the contained material, across the same face, upon the surrounding material. Similar considerations will apply in regard to the other faces.

Confined our attention to the forces which are exerted upon the contained material, let us denote by \( P \) the resultant force exerted by the total action across the face ABD'. Whether the elastic solid as a whole be in equilibrium or in motion, the magnitude of \( P \) will depend upon the area of this face; but the quantity defined by

\[
P = \frac{\text{Area of ABD'}}{1}
\]

is limited in the main by the extent to which actual materials may be considered to satisfy its fundamental assumption—that their behaviour under applied forces is independent of their previous history. It is doubtful whether perfect elasticity, as thus defined, is exhibited by any actual material. Thus, the behaviour of wood under applied forces is dependent to a considerable extent upon its dryness and temperature, and of rubber upon the forces to which it has recently been subjected; most metals and other crystalline materials possess practically perfect elasticity under small forces, but their behaviour depends in part upon their previous history when the forces exceed certain limits.

§ (3) STRESS AND STRAIN.—In the development of the precise mathematical theory it is found convenient to introduce two new physical concepts, for which we employ the terms "stress" and "strain." To understand these terms, we may consider the motion or equilibrium of that portion of an elastic solid which is contained within the volume of the small parallelepiped indicated in Fig. 1. The contained material will in all practical instances be subjected to body forces such as gravity, and to balance these (and also to overcome its inertia, if the material is in accelerated motion), forces must be exerted across the containing faces by the surrounding material. We need not concern ourselves here with the difficult physical problem of explaining the mechanism by which these forces are exerted; it is sufficient for our purpose to remark that the action, whatever it is, must be of a reciprocal nature; that is to say, the force which is exerted upon the contained material, across the face ABD', by the surrounding material must be equal and opposite to the forces which is exerted by the contained material, across the same face, upon the surrounding material. Similar considerations will apply in regard to the other faces.

Confined our attention to the forces which are exerted upon the contained material, let us denote by \( P \) the resultant force exerted by the total action across the face ABD'. Whether the elastic solid as a whole be in equilibrium or in motion, the magnitude of \( P \) will depend upon the area of this face; but the quantity defined by

\[
P = \frac{\text{Area of ABD'}}{1}
\]
will tend to a definite (and in general finite) limit as the area is indefinitely reduced, and to this limit we give the term "strain." The dimensions of a stress can evidently be represented by \([\text{MP}^{1/2}]\); and it is clear from the expression (1) that it shares many of the properties of a force. It has magnitude and direction, and the stresses acting on a given surface can be resolved and compounded by the vector law: further, from what has been said above, it is really a quantitative expression for the intensity, not so much of the action on any definite portion of the material, as of the mutual action between the two portions of material which are separated by a specified surface.

Just as the idea of "stress" is an extension, for the special purposes of our subject, of the familiar concept of mechanics, so "strain" is a development of the purely kinematic concept of relative displacement. Reverting to Fig. 1, we assert that the material under consideration will be deformed, whatever its motion may be, so long as the volume occupied by any definite part of it remains unchanged both in size and shape; the motion of unstrained bodies is thus the province of rigid dynamics. On the other hand, if we consider the material which in one configuration is contained within the parallelepiped ABDQEP, and if in a second configuration the same material is contained within a volume of different size and shape, then we may say that the second configuration can be obtained from the first by a process involving strain.

Confining our attention to the edges of the original parallelepiped, we notice that strain may involve a change in one or more of the lines AB, BD, ..., etc., or in one or more of the angles CAB, CBA, ..., etc., or in both. Stretching of the material in the direction of the axis AB will be accompanied by a change in the length of AB. Let A' and B' denote the new positions of the points A and B; then the fractional alteration in the length of AB will be given by

\[ e = \left( \frac{A'B' - AB}{AB} \right) \quad (2) \]

and while both the numerator and the denominator of this expression tend to zero in the limit, as the length AB is indefinitely reduced, their ratio will tend to a limit which must be finite (if we exclude the possibility of discontinuous displacements, which would involve rupture of the material), but will not generally be zero. To this limit we attach the definitive term "stretch": it is clearly a non-dimensional and scalar quantity.¹

¹The term "extension" is also used to denote this quantity.

In much the same way, we may measure the change in the angle CAE by the expression

\[ \gamma = \angle CAE - \angle CA'E' \quad (3) \]

For strict conformity with (2), we ought, of course, to divide the quantity on the right by the original magnitude of the angle. But owing, probably, to the fact that \(\gamma\) as defined in (3), is already a non-dimensional scalar quantity, it has become customary to dispense with this qualification, and to define \(\gamma\) as the value of the expression (3) when the original angle CAE is specified to be a right angle. We thus obtain the concept of a second type of strain, to which is usually given the term "shear-strain," or "slip."

§ (4) Inter-Relation of Stress and Strain. Hooke's Law. Principle of Superposition.—Making use of the terms to which we have thus defined, we may say that the theory of elasticity is concerned with the determination of the stresses and strains which occur in a body under the action of applied forces, and the fundamental assumption explained in § (2) may be correspondingly expressed by saying that a perfectly elastic solid stress will accompany any given strain, and vice versa. We must now refer to another assumption, totally different both in nature and importance, although in the development of the theory it has become almost as fundamental as the assumption of perfect elasticity. This asserts that the relation between stress and strain is one of direct proportionality. That the assumption is representative of real materials was first discovered, in 1678, by Hooke, and the relation is for this reason commonly known as "Hooke's Law."

To give precision to "Hooke's Law," the constant of proportionality requires to be stated, and we must therefore consider what are the possible types of stress and of strain. We have seen in § (3) that the total stress across any imaginary surface in a body can be resolved into components by the vector law. Let us then resolve in directions normal and tangential to the surface. The first component may be termed a "normal stress," since it constitutes an action between the two portions of material which lie on opposite sides of the surface, tending to resist their relative motion in a direction normal to the surface; if the action tends to prevent their separation it is termed a "tensile stress," and if it tends to resist their approach, a "compressive stress." The convenience of these terms is obvious, since they describe the stresses which occur on cross-sections of a straight rod under the action of external tension and compression respectively.

For a component stress of which the direction is parallel to the surface it is usual to employ the terms "tangential" or "shear stress." These terms describe an action between the two portions of material lying on opposite sides of the surface, which tends to prevent them from sliding relatively to one another, without separation; it will be realised, therefore, that shear stress is brought into action,
by solid friction, at the surface of two bodies which are in contact and sliding relatively to one another.

Before proceeding further, it will be convenient to introduce a notation for the component stresses which we have just discussed. Let us consider the action at the face OBCF of the elementary parallelepiped of Fig. 1, and let the force exerted on the parallelepiped by the material which lies on the x-face of this face be resolved into components P_x, P_y, and P_z, parallel to the axes Ox, Oy, Oz respectively. Corresponding to the components P_x and P_y, we have tangential stresses, which we may denote by Z_x and Z_y respectively; and corresponding to P_z we have a normal stress, which we denote similarly by Z_z. It will be evident that in this notation the capital letter defines the face on which the stress is in question acts, whilst the suffix denotes the direction of the force.

Passing through every point in the material we have three mutually perpendicular faces of the kind just considered, and on each there are three independent components of stress which require symbols. Nine stress-components are thus introduced, namely, three normal stresses, X, Y, Z, and six tangential stresses, X_x, X_y, X_z, Y_x, Y_y, Y_z, Z_x, Z_y, Z_z. But the last six can be reduced to three, since we may show that

\[ X_x = Y_x, \quad Y_y = Z_y, \quad Z_z = X_z, \quad \ldots \quad (4) \]

These relations may be proved by considering the equilibrium of an elementary parallelepiped, such as is shown in Fig. 2, which requires, after suit,

![Diagram](image)

that there shall be no tendency to rotate. A little reflection shows that body forces such as are exerted by gravity, if of finite intensity, have a negligible turning effect, and that the only components of stress which have a tendency to turn the parallelepiped about the axis YY (if the dimensions of the faces are so small that the resultant force corresponding to any stress can be assumed to act at the centre of the face affected) are the components X_x on the two faces which are normal to the x-axis, and the components Z_z on the two faces which are normal to the z-axis. The total forces contributed are, for the former stresses, of magnitude \( (X_x, AC, AD) \) (we have to multiply the stresses by the areas of the faces upon which they act), and for the latter, of magnitude \( (X_z, AB, AC) \), as shown. Now the first two forces act in opposite directions along lines which are a distance AB apart, and the second in opposite directions along lines which are a distance AD apart: thus the first pair produces a couple of magnitude \( (X_x, AB, AC, AD) \), and the second a couple of magnitude \( (X_z, AB, AC, AD) \), and (as is evident from the diagram) of opposite sign. The condition of equilibrium therefore requires that

\[ Z_x, AB, AC, AD = X_z, AB, AC, AD, \]

whence the third of the relations (4) follows directly, and the other two relations by similar reasoning.

It can be shown that the stress-components defined as above, and reduced in number by the relations (4), in six, are sufficient for representing the most general system of stress which can obtain at any point in a body. By means of certain "formula of transformations," the stress-components on any other plane through the point can be written down, and it may be shown that in any possible system of stress there will be three planes through any point, mutually perpendicular, on which the stresses are purely normal. Hence, in proceeding to derive the exact stress-strain relations required to give precision to Hook's Law, we may confine our attention to a system of these mutually perpendicular normal stresses.

Notation is similarly required for the different components of strain. In § (3) we considered two distinct types, to which we gave the names "stretch" and "slipe." We now introduce the notation \( e_x \) for the stretch in the direction of the axis x—the suffix double indicating that the strain in question is a relative displacement of two planes, each of which is perpendicular to the axis of x; and in conformity with this notation we employ the symbol \( e_\gamma \) for the angle \( \gamma \) defined in (3)—the double suffix here indicating that the strain in question is a relative displacement of planes which are perpendicular to the axes y and \( \gamma \) respectively. It is obvious that

\[ e_\gamma = e_x, \quad e_y = e_\gamma, \quad e_z = e_\gamma, \quad \ldots \quad (5) \]

so that corresponding to our six distinct components of stress we have six distinct components of strain. These may be shown to be sufficient for defining the most general type of strain which can obtain at any point. By means of "formula of transformations" similar to those which we have noticed above, for bodies in which we have allowed no sliding for stresses, we can express in terms of \( e_\gamma \), \( e_y \), \( e_z \), etc., the strain-components corresponding to any other system of axes, and we may prove that in any possible system of strain there will exist three directions through any point which are mutually perpendicular, both before and after strain; the strains in these directions are termed "principal strains" at the point considered, and the directions themselves are termed "principal directions of strain."

Considerations of symmetry show that the principal directions of strain will always coincide, in materials which are isotropic, i.e., which exhibit similar properties in all directions,—with the directions of the three purely normal stresses to which we have referred above; we shall therefore define our strain relations completely if we can write down relations between the three "principal stresses," as they are generally called, and the corresponding "principal strains." We begin by considering the strain system which is involved by a simple tensile stress, of amount
ELASTICITY, THEORY OF

T1. This stress will evidently be one of the three principal stresses at the point considered, and the other two will be zero; it might be expected, therefore, that two of the three corresponding principal strains will vanish. Experiment shows, however, that the facts are different: the tension T1 is accompanied by a proportionate strain in its own direction, together with proportionate contractions (i.e. stretches of negative sign) in directions perpendicular to this. That is to say, if we choose our axis of x to coincide with the direction of T1, then corresponding to the strain-system

\[ \begin{align*}
X_x &= T_1, & Y_y &= Z_z &= 0,
\end{align*} \]

we have the strain-system

\[ \begin{align*}
\varepsilon_{x} &= \frac{T_1}{E}, & \varepsilon_{y} &= \varepsilon_{z} &= -\frac{\sigma_{z}}{E},
\end{align*} \]

where E and \( \sigma_{z} \) by Hooke's Law, are constants of the material.

The quantity E is known as Young's Modulus. It evidently has the dimensions of a stress, and may in fact be defined as the stress which, acting alone, would involve a stretch of magnitude 1—i.e. a doubling of the distance between any two points in the material—measured in its own direction.\(^1\) On the other hand, the quantity denoted by \( \sigma_{z} \) is non-dimensional, being the ratio of the lateral contraction (\( -\varepsilon_{z} \)) to the longitudinal extension (\( \varepsilon_{x} \)); it is known as Poisson's Ratio, and the fact that it has finite values in actual materials introduces very considerable complexity into the calculations of elastic theory.

Similar expressions will give the strain-systems which correspond to tensile stresses acting in the directions of Oy or Oz; thus, corresponding to the strain-system

\[ \begin{align*}
X_x &= 0, & Y_y &= T_1, & Z_z &= 0,
\end{align*} \]

we have the strain-system

\[ \begin{align*}
\varepsilon_{x} &= -\frac{T_1}{E}, & \varepsilon_{y} &= \frac{\sigma_{y}}{E}, & \varepsilon_{z} &= -\frac{\sigma_{z}}{E},
\end{align*} \]

and corresponding to the strain-system

\[ \begin{align*}
X_x &= Y_y = 0, & Z_z &= T_1,
\end{align*} \]

we have the strain-system

\[ \begin{align*}
\varepsilon_{x} &= \varepsilon_{y} = -\frac{T_1}{E}, & \varepsilon_{z} &= \frac{\sigma_{z}}{E},
\end{align*} \]

The most general system of stress, as we have seen, will involve three principal stresses at every point, and by a suitable choice of axes it can be written in the form

\[ \begin{align*}
X_x &= Y_y = Z_z &= 0,
\end{align*} \]

where \( \lambda = \frac{1}{1+\epsilon} \) represents the fractional change of volume which will be produced in an elementary parallelepiped of the material, as the result of the three strains \( \epsilon_{x} \), \( \epsilon_{y} \), and \( \epsilon_{z} \) occurring simultaneously, if we may regard these strains as small; for this fractional change is given by

\[ \lambda = \frac{1 + \epsilon_{x} + \epsilon_{y} + \epsilon_{z}}{1 + \epsilon_{x} + \epsilon_{y} + \epsilon_{z}} \]

which is known as the dilatation. Obviously, \( \lambda \) represents the fractional amount of volume which will be produced in an elementary parallelepiped of the material, as the result of the three strains \( \epsilon_{x} \), \( \epsilon_{y} \), and \( \epsilon_{z} \) occurring simultaneously, if we may regard these strains as small; for this fractional change is given by

\[ \lambda = \epsilon_{x} + \epsilon_{y} + \epsilon_{z} \]

if we neglect small quantities of order higher than the first. By addition of the three equations (12) we have

\[ X_x + Y_y + Z_z = (3\lambda + 2\mu)\Delta, \]
and if the three stresses $X$, $Y$, and $Z$ are equal, and of magnitude $E$, this equation may be written in the form

$$
\Delta = \frac{3F}{2n} = \frac{E}{(1-2\nu)^2} \cdot \cdot \cdot (13)
$$

which gives the fractional increase of volume caused by a stress of uniform intensity $T$ in all directions. A stress of this nature, but negative in sign, is produced by the action of hydrostatic pressure; the fractional change of volume is also negative, i.e., a contraction; and the quantity $\frac{1}{3}(3X+2Y)$, which evidently corresponds in equation (12) to the quantity $G$ in the expression (6) for $\sigma_{xx}$, is by analogy termed the Modulus of Compression, or Bulk Modulus, of the material. It is often convenient to have a special symbol for the quantity, although it is not an independent constant of the material, and the symbol usually employed is $K$; we have, from (12) and (13),

$$
K = \frac{1}{3}(3X+2Y) = \frac{E}{(1-2\nu)^2}. \cdot \cdot \cdot (14)
$$

Another constant of frequent occurrence, also expressible in terms of $E$ and $\nu$, is the "modulus of rigidity," often denoted by $C$ or $N$. We may conceive a stress-system such that a small cube of the material is completely free from stress on two opposite faces, and subjected to simple shear, of intensity $S\nu$, on the other four; the relations (2) show that the shears on one pair of opposite faces must be equal to the shears on the other pair, and we may therefore take Fig. 3 as representing the stress-system. If we consider the corresponding stress across the diagonal surface $ABC$, it is easy to show, from the condition for equilibriun of the two parts into which this surface divides the cube, that it will be purely normal, tensile, and of intensity $S$; similarly, the stress on the other diagonal plane will be purely normal, compressive, and of intensity $S$. If, therefore, we take our axes of $x$, $y$, and $z$ parallel to $BF$, $BA$, $AD$ respectively, we see that the stress-system will be given by

$$
\begin{align*}
X_x &= S; & Y_y &= -S; & Z_z &= 0; \\
X_y &= Y_z &= Z_x &= 0,
\end{align*}
\cdot \cdot \cdot (15)
$$

and the corresponding strain-system, by (10), will be given by

$$
\begin{align*}
\varepsilon_{xx} &= \frac{1}{E} (1 + \nu) S = - \varepsilon_{yy}, \\
\varepsilon_{yy} &= \frac{1}{E} (1 + \nu) S = - \varepsilon_{xx}, \\
\varepsilon_{zz} &= 0.
\end{align*}
\cdot \cdot \cdot (16)
$$

Thus we see that the diagonal $BF$ will lengthen by a fractional amount $\frac{1}{E} (1 + \nu) S$, and that the diagonal $AB$ will contract by a like amount. The two diagonals will remain perpendicular, and if dashes indicate positions after strain, we have

$$
\begin{align*}
\tan \angle \Delta'BC &= \tan \angle \Delta'AC = \frac{1 + \nu}{1 - \nu} S = \frac{1}{E} \cdot \cdot \cdot (17)
\end{align*}
$$

and this change is the angle $\gamma$ of shear strain, or "slide," as defined in equation (3) of § 3. Thus we have

$$
\begin{align*}
\gamma &= \frac{\pi}{2} - \tan^{-1} \left( \frac{1 + \nu}{1 - \nu} S \right), \\
whence \quad \tan \gamma &= \frac{\varepsilon_{xx} - \varepsilon_{yy}}{2 + \varepsilon_{xx} + \varepsilon_{yy}}, \\
&= \frac{S}{1 + \nu}
\end{align*}
\cdot \cdot \cdot (18)
$$

if we regard the strains as small, and neglect small quantities of the second order. To the same approximation, we may write $\gamma'$ for $\tan \gamma/2$; we thus obtain, finally,

$$
\begin{align*}
\gamma &= \frac{S}{1 + \nu} \\
&= \frac{E}{(1 + \nu) K}
\end{align*}
$$

and by comparing (17) with (18) we see that

$$
\frac{S}{1 + \nu} = 2 \frac{S}{1 + \nu} K
$$

that is to say, the modulus of rigidity $C$ (or $N$) is identical with the constant $K$ of equation (12).

The results expressed by (14) and (10) enable us to impose certain limits upon the values which are possible for $\nu$. It is clear that the three moduli denoted above by $K$, $C$, and $E$ must all be positive; otherwise, it would be possible to obtain an indefinite supply of energy from elastic material by putting it through an appropriate cycle of stress, and the principle of Conservation of Energy would be violated. It follows that the two ratios $K/E$ and $C/K$, and hence the quantities $1 - 2\nu$ and $1 + \nu$ are necessarily positive; that is to say, $\nu$ must lie within the range given by

$$
-1 < \nu < 0.
$$

So far as is known, no material exhibits a negative value of $\nu$; but it is of interest to note that such values are not $a priori$ impossible.

If our axes of $x$ and $y$ had been taken parallel to the sides, $EB$, $EA$, instead of to the diagonals, $BF$, $BA$, of the cube, the stress-system of Fig. 3 could have been expressed in the form

$$
\begin{align*}
X_x &= S; & Y_x &= Z_x &= 0 \\
X_y &= Y_y &= Z_y &= 0
\end{align*}
\cdot \cdot \cdot (19)
$$

and the corresponding strain-system, by (10), will be given by

$$
\begin{align*}
\varepsilon_{xx} &= \frac{1}{E} (1 + \nu) S = - \varepsilon_{yy}, \\
\varepsilon_{yy} &= \frac{1}{E} (1 + \nu) S = - \varepsilon_{xx}, \\
\varepsilon_{zz} &= 0.
\end{align*}
\cdot \cdot \cdot (20)
$$

Thus we see that the diagonal $BF$ will lengthen by a fractional amount $\frac{1}{E} (1 + \nu) S$, and that the diagonal $AB$ will contract by a like amount. The two diagonals will remain
and the corresponding strain system, from what has just been said, would have been given by
\[
\begin{align*}
\varepsilon_{xx} &= \frac{S}{\mu} = \varepsilon_{yy} = \varepsilon_{zz} = 0, \\
\varepsilon_{yz} &= \gamma, = \varepsilon_{xz} = 0.
\end{align*}
\] (21)

The strains corresponding to shear-stress components \( Y_z \) or \( Z_z \) could be similarly written down, and by the Principle of Superposition these may be combined with one another, and also with the expressions (11) or (12), which in \( \xi \) were derived on the assumption that \( X_x, Y_y, Z_z \) were principal stresses—i.e., that \( X_x, Y_y, Z_z \) were zero; for the principle asserts that any one stress-component has a definite expression in terms of the strain-components, which will not be affected by the existence of any other. Thus, in the general case, where the axes of \( x, y, z \) do not coincide with the directions of the principal stresses, we have the following relations between stress and strain:
\[
\begin{align*}
X_x &= \lambda \varepsilon_x + 2\mu \varepsilon_{xx}, \\
Y_y &= \lambda \varepsilon_y + 2\mu \varepsilon_{yy}, \\
Z_z &= \lambda \varepsilon_z + 2\mu \varepsilon_{zz}.
\end{align*}
\] (22)

The most general expression of Hooke's Law, in isotropic material, is thus seen to involve only two elastic constants.

6. DYNAMICAL EQUATIONS IN TERMS OF STRESS—We have now expressed the purely empirical law of Hooke in a form which is mathematically convenient, and we may proceed to apply our results to the analysis of stress and strain in elastic solids. The motion of any portion must be governed by the ordinary laws of dynamics; that is to say, its acceleration will be determined by the resultant unbalanced force which acts upon it, and by its inertia. If we consider the portion contained within the boundaries of a small parallelepiped, as shown in Fig. 4, it is clear that we can express the unbalanced force exerted by the surrounding material in terms of the stress-components defined above. Consider, in the first place, the component of this force which acts in the direction of the axis \( Ox \). The stress-components which contribute to it are \( X_x, Y_y, Z_z \), acting on the faces shown. The components \( X_x \) act on faces whose area is \( \delta y \times \delta z \), and which are a distance \( \delta x \) apart, so that the magnitudes of the stresses on the two faces (which clearly lead to pull the parallelepiped in opposite directions) differ by the amount \( \delta X_x \). Hence, their combined contribution to this force is
\[
\frac{\partial X_x}{\partial x} \delta x \ : \ \delta y \ : \ \delta z.
\]
The contributions of the other stress-components are given, similarly, by
\[
\frac{\partial Y_y}{\partial y} \ : \ \frac{\partial Z_z}{\partial z} \ : \ \delta x \ : \ \delta y \ : \ \delta z,
\]
and hence we see that the total unbalanced force on the parallelepiped, in the direction \( Ox \), is given by
\[
(pX + \frac{\partial X_x}{\partial x} + \frac{\partial X_y}{\partial y} + \frac{\partial X_z}{\partial z}) \delta x \ : \ \delta y \ : \ \delta z,
\]
where \( pX \) is the body-force per unit volume, acting at the point considered; the substitution of \( X_x, X_y, X_z \) for \( X, Y, Z \) is justified by the relations (4) above.

But the mass of the material contained within the parallelepiped in \( p, x, y, \delta y, \delta z \), where \( p \) is the density; hence, if \( f_o \) is its acceleration in the direction \( Ox \), we have the equation of motion in this direction
\[
\left\{ \begin{align*}
pX + \frac{\partial X_x}{\partial x} + \frac{\partial X_y}{\partial y} + \frac{\partial X_z}{\partial z} = \rho \cdot f_x
\end{align*} \right\}
\]
and the equations
\[
\left\{ \begin{align*}
pX + \frac{\partial X_x}{\partial x} + \frac{\partial X_y}{\partial y} + \frac{\partial X_z}{\partial z} = \rho \cdot f_y
\end{align*} \right\}
\]
and
\[
\left\{ \begin{align*}
pX + \frac{\partial X_x}{\partial x} + \frac{\partial X_y}{\partial y} + \frac{\partial X_z}{\partial z} = \rho \cdot f_z
\end{align*} \right\}
\]
can be obtained similarly.

Equations (23) must obviously be satisfied at every point in a body, independently of any assumption regarding its elasticity. No additional equations are required to define the translational motion of the parallelepiped, which may ultimately be regarded as infinitesimal, and so treated as a particle. The absence of any resultant turning tendency has been ensured already, by the relations (4).

7. STRAINS EXPRESSED IN TERMS OF DISPLACEMENT—When the stress-strain relations are known for the material considered, we can express the quantities (other than \( X_x, Y_y, Z_z \)) on the right of equations (23) in terms of strain-components; but the equations will still be intractable mathematically, unless we can find a common system of variables in terms of which they may be completely expressed; and the fact that the acceleration components \( f_x, f_y, f_z \) may be expressed in terms of the component displacements of the point considered indicates that we should endeavor also to relate the six strain-components to these quantities.

Let \( u, v, w \) denote the component displacements.
ELASTICITY, THEORY OF

ments of any point \((x, y, z)\) in the directions \(Ox, Oy, Oz\) respectively; thus
\[
\begin{align*}
\hat{e}_x &= \frac{\partial u}{\partial x}, \\
\hat{e}_y &= \frac{\partial v}{\partial y}, \\
\hat{e}_z &= \frac{\partial w}{\partial z}.
\end{align*}
\] (24)

The strain-component \(\hat{e}_x\) denotes the stretch in the direction \(Ox\), and this term was defined in §(3) as the limiting value of the expression (2) when \(AB\) is parallel to \(Ox\) and indefinitely reduced. We may now write \(\Delta x\) for the length \(AB\) in the denominator; the numerator is the total increase in the length of \(AB\) which results from strain, and this will clearly be equal to the amount by which the displacement of the point \(B\) exceeds the corresponding displacement of the point \(A\)—i.e. to the quantity \((\hat{u}_x\hat{u}_x)\Delta x\). Thus, in the limit, when \(\Delta x\) is indefinitely reduced, we have
\[
\hat{e}_x = \frac{\hat{u}_x \Delta x}{\Delta x} = \hat{u}_x.
\]
and similarly
\[
\hat{e}_y = \hat{v}_y, \quad \hat{e}_z = \hat{w}_z.
\] (25)

The strain-component \(\hat{e}_y\) denotes the slide in the \((y, z)\) plane, i.e. the value of \(\gamma\) in equation (3), when \(AB\) is initially parallel to the axis of \(y\), and \(AC\) to the axis of \(z\). It is the angle by which \(AB\) and \(AC\) approach one another, and this obviously is the sum of (i.) the angle at which \(\Delta AB\) is inclined, after strain, to the \(y\)-axis, and (ii.) the angle at which \(\Delta AC\) is inclined, after strain, to the \(z\)-axis. By reasoning similar to what has been given above, we may show that the first angle is of magnitude \(\hat{u}_y \hat{u}_z\) (we shall always be concerned with strains which are very small, and hence it is unnecessary to distinguish between the angle and its tangent) and the second of magnitude \(\hat{w}_y \hat{w}_z\); hence we have
\[
\hat{e}_y = \frac{\hat{u}_y \hat{u}_z}{\hat{u}_y + \hat{u}_z},
\]
and similarly
\[
\hat{e}_z = \frac{\hat{w}_y \hat{w}_z}{\hat{w}_y + \hat{w}_z}.
\] (26)

Making use of the results expressed in equations (22) and (24)-(26), we can write the equations of motion (23) in terms of the three variables \(u, v, w\), and of constants which are known for the material considered. We thus obtain the result given in equations (28).

The fact that all six of the strain-components can be expressed in terms of the three component displacements \(u, v, w\) indicates that these six quantities are to some extent interconnected; that is to say, if we assign an arbitrary expression to each strain-component, we shall not in general obtain a possible distribution of strain. It is not difficult to see that the reason why such arbitrary expressions are not permissible is that they violate the conditions for continuity of the material after strain.

The necessary and sufficient relations which must be satisfied by the strain-components, in order that the corresponding system of displacements may be a possible one, can be written as follows:
\[
\begin{align*}
\hat{e}_x &= \frac{\partial u}{\partial x}, \\
\hat{e}_y &= \frac{\partial v}{\partial y}, \\
\hat{e}_z &= \frac{\partial w}{\partial z}, \\
\hat{e}_x &= \hat{u}_x, \\
\hat{e}_y &= \hat{v}_y, \\
\hat{e}_z &= \hat{w}_z.
\end{align*}
\] (27)

These equations are generally known as the "Conditions of Compatibility for Strain-Components." They can be verified by substitution from (25) and (26), and are obviously independent of any assumption in regard to the properties (other than continuity) of the material.

§ (8) EQUATIONS OF MOTION.—Reviewing the position reached in the preceding paragraphs, we notice that—

(a) The equations which express the equilibrium or motion of the material contained within any elementary parallelepiped may be written down from considerations of statics or of dynamics, in terms of its density and of the stresses which act upon its faces;

(b) The component velocities and accelerations of the contained material can be expressed in terms of the component displacements \(u, v, w\);

(c) The strains (or changes in the sides and angles of the parallelepiped) may be expressed in terms of the same three quantities, from geometrical considerations alone;

(d) An innovation is introduced in the theory of elasticity, by the assumption of relations between stress and strain which enable us to substitute strains for stresses in the equations of equilibrium or of motion, and thereby to express these equations solely in terms of the relative displacements of different points in the body.

The resulting equations of motion, when the body-forces are zero or negligible, may be written in the form
\[
\begin{align*}
\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} &= 0, \\
\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} &= 0, \\
\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} &= 0.
\end{align*}
\] (28)

where \(\nabla^2\) denotes the operator
\[
\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}
\]
and the " dilatation "
\[
\Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}
\]
When the displacements, \( x, y, z \), are steady, the terms on the right of these equations vanish; we are then left with "equations of equilibrium."

For some purposes it is convenient to replace the rectangular (or Cartesian) system of coordinates which we have employed above by other systems, such as polar coordinates. For particulars of such systems, reference must be made to the authors cited at the foot of this article; it is sufficient here to state that the motion can always be defined by three variables, between which three independent relations may be found from the equations of motion for the material contained within an elementary volume.

The equations (28) will be satisfied at every point in an elastic body, on the assumption that the relation between stress and strain may be expressed as in § (9) above (i.e. that it is linear, and independent of the previous stress-history of the material), and that the strains occurring in the body are everywhere small. The latter assumption is necessary both to justify the equations of equilibrium as expressed in terms of stresses, and to give precision to the relationship between stress and strain; fortunately, it imposes no serious restriction upon the extent to which our results may be applied in practice, since it is found that the strains produced in actual materials, by any stress which they are able to sustain elastically, are always extremely small. Remembering this restriction upon the validity of the equations, we may draw a deduction of great practical importance from their form; for it is evident that when any two solutions are combined in any proportion, the resulting expressions for the displacements will also be solutions of the equations. This is, of course, a restatement, in a general and mathematical form, of the "Principle of Superposition" which we have noticed, in an experimentally established law, in §§ (4) and (9) above.

We have said that the general problem in the theory of elasticity is to determine the relative displacements of different points in a given body, produced by forces which are specified as acting either on its surfaces or throughout its volume: forces of the first type are termed surface tractions, and of the second type body forces. A second form of the problem may now be mentioned, in which the displacements of the surface are specified: body forces may also be assumed to act, and in general the specified conditions may include specified tractions at some points of the boundary, and specified displacements at others. The surface displacements or tractions may be specified by their components perpendicular and parallel to the surface, but the displacements can obviously be resolved along any specified direction (and hence expressed in terms of \( u, v, \) and \( w \)), and the formula for transformation of stress-components (referred to in § (4) above) enables us to express boundary conditions which consist of specified surface-tractions in terms of the stress components, \( X_x, X_y, X_z \), etc., and hence in terms of \( u, v, \) and \( w \).

Mathematically, therefore, our general problem is to determine the forms of three functions, \( u, v, w \), which must satisfy the equations (28) of motion or equilibrium at every point in the body, and which are subject to certain boundary conditions at the surface. If such functions can be found, we are in a position immediately to deduce the strains and stresses which occur at every point in the elastic solid considered, and the behaviour is then completely defined: for Kirchhoff has shown that any solution of the equations of equilibrium, which also satisfies the specified boundary conditions, is unique, and Neumann has extended his theorem to the equations of motion, by showing that a solution of these equations which satisfies specified initial conditions in regard to displacement and velocity is also unique.

For practical purposes, we are often concerned almost entirely with the distribution of stress in the interior of an elastic body, and the displacements and strains which accompany the stress are of little interest. When the surface tractions are specified, it is, therefore, evident that a considerable gain in point of convenience might be expected from methods which would enable us to calculate the stresses directly, without introducing the quantities \( u, v, \) and \( w \). Much attention has been devoted in recent years to this problem, and methods for the "direct determination of stress" are coming into more and more frequent use. Their principle consists in expressing the different components of stress in terms of one or more common functions, which are determined by characteristic differential equations obtained at every point, and by appropriate boundary conditions: for details, reference must be made to the authors cited.

§ (9) APPLICATION OF THEORY TO ENGINEERING DESIGN. The theory, of course, provides an interest, from the purely mathematical standpoint, which is independent of its practical applications: but for the purposes of the present article it is necessary here to inquire what is its value to the physicist and to the engineer. The immediate answer, from the point of view of the engineer, is that the calculation of stresses is an essential preliminary to the design of structural members of adequate strength. Actual materials, as has been stated above, are elastic only so long as the stresses to which they are subjected lie within certain definite limits: if these limits are exceeded, permanent distortion occurs, by processes of great complexity, about which it is unnecessary to say more here than that they are invariably accompanied by more or less serious deterioration of the materials' capacity for resisting stress. The problem of deciding
whether the calculated stress-system will or will not produce this " failure of elasticity " in a given material is one with which the theory of elasticity, in its strict sense, has nothing to do; it is fully discussed in the article on "Theory of Structures," and it is sufficient here to remark that the theory of elasticity supplies the mathematical basis for the calculation of stresses; that the science of Testing of Materials (see article under this heading) supplies experimental data in regard to the strength of the materials of construction; and that the Theory of Structures employs the information thus provided in the practical science of " Design."

§ (10) SOME GENERAL THEOREMS. — Apart from questions of strength, the practical utility of the theory of elasticity will be most easily judged from an account of the problems which have been solved up to the present time by its means. We may notice, in the first place, certain general theorems which have been established. First, it has been shown that the stresses set up by a load which is suddenly applied may be as much as twice as great as those which would be produced by a gradual application of the same load, and that if a load be suddenly removed the stresses may be trebled; this result has, of course, a very great importance for engineering design. Again, the effects of small flaws in materials have been investigated, and it has been shown, for example, that if a member which is subjected to simple tension or compression in one direction contains a small spherical flaw at some point in its interior, the tension or compression in the material will be approximately doubled at certain points on the surface of the flaw; if the flaw have the form of a circular cylinder, with its axis perpendicular to the direction of the tension, the stresses will be trebled.

Again, the effect of an impulsive pressure at the surface of a body has been investigated in general terms, and it has been shown that waves of stress can be propagated in an elastic solid which, if the solid is isotropic, may be of two types, propagated with different velocities. The first is a wave of dilatation, involving an alteration in the volume, but not in the shape, of each element of the material as the wave passes it; such waves are propagated with a velocity \( \sqrt{\lambda/2\alpha} \). The second is a wave of distortion, involving change of shape, but no change of volume in each element affected; such waves travel with velocity \( \sqrt{\alpha/\beta} \). Further, it has been shown that a certain type of wave exists which is propagated over the surface of a solid body, and involves practically no disturbance in the interior; its velocity is a little less than that of the waves of distortion just referred to. These results have, of course, an important bearing upon the phenomena which occur in the collision of elastic solids, and in earthquakes.

Light has also been thrown upon the nature of the stresses produced by concentrated loads at some point in a body, by means of exact solutions for certain particular examples; and a knowledge of the velocity with which a wave of stress is propagated along a thin cylindrical rod has been used by Hopkinson in devising apparatus for the measurement of the large impulsive pressures which are set up in the detonation of explosives.

§ (11) SPECIAL SOLUTIONS. PRINCIPLE OF ST. VENANT. — Turning now to the consideration of special solutions of the equations of equilibrium and of motion, we may notice that exact solutions have been found for several types of periodic vibration in spheres and circular cylinders, and that the equations of equilibrium have been solved in a form which provides exact knowledge of the stresses produced in a prismatic body of any cross-section, under certain particular systems of loading, of which the general effect is to produce extension, flexure, or twisting; these results, as will be seen later, have been extended to give an approximate theory of such sections, without restriction upon the exact distribution of the loads which produce them. We also possess exact solutions for the stresses set up in thick shells, or in spherical shells, by uniform tractions applied to their surfaces, and for the stresses which are produced by the rotation about their axes of certain solids of revolution such as cylinders and thin discs.

In these exact solutions, it is sometimes necessary to assume that a small " auxiliary stress-system " acts at certain parts of the boundary, and the results thus fail to apply exactly to practical problems, in which such systems cannot be assumed to exist; but St. Venant has shown that the discrepancy which thus arises may be, for practical purposes, regarded as involving a slight and unimportant decrease of accuracy, rather than a loss of generality. The principle upon which he bases this conclusion, and which is usually designated by his name, states that any locally applied system of surface tractions, which is itself a completely equilibrating system, has a negligible influence upon the stresses, except at points of the body lying quite close to the region within which the system is applied.

§ (12) PROBLEMS OF THE SPHERE AND OF THE PLANE. — General solutions have also been obtained for the stresses produced by symmetrical distributions of surface traction acting upon circular cylinders or spheres, and the solutions found in the latter case have been applied to problems relating to the form of the earth, such as the dependence of its ellipticity of figure upon the diurnal rotation, and the relative displacements produced by the
disturbing attractions of the sun and moon. The latter are analogous to the tidal motion of the sea relative to the land, and for this reason have been called "tides." Lord Kelvin has calculated what he has termed the "tidal effective rigidity of the earth."—i.e. the rigidity which must be attributed to a homogeneous, incompressible solid sphere, of the same size and mass as the earth, in order that tides in a region of the actual ocean resting upon it may be of the same height as the observed oceanic tides. His calculations led him to interesting speculations as to the constitution of the earth, which do not, however, appear to be entirely supported by evidence obtained from tidal phenomena.

Finally, we may notice that solutions have been obtained for the effects of certain particular distributions of surface traction upon a body of infinite extent, having one plane boundary; it does not appear, however, that these results are of much practical importance.

§ (13) Approximate Results. The practical value of the theory of elasticity has been extended less by discovery of exact solutions, such as have been referred to above, than by investigations which have shown that increased generality can be obtained at the cost of some slight loss in accuracy. For the practical purposes of physics or engineering, it will be recognized that generality is of much greater value than absolute accuracy, since a margin of safety has in many cases to be provided, to meet such contingencies as faulty workmanship, corrosion, or local damage. We have already referred to the value of St. Venant's principle in this connection: one of its most important applications has been to the theory of such problems as the stresses in beams and thin plates. The exact solutions for the stresses produced by forces in a uniform beam, to which reference has been made in § (11), show that the resultant action of the stresses occurring on any section of the beam may be expressed in terms of the extension and curvature, at that section, of its strained centro-line (i.e. the line through the centroids of cross-sections). It may be shown that St. Venant's principle justifies us in assuming that these expressions will obtain, with reasonable accuracy, even when the external forces are not applied in the manner postulated by the exact solutions, or when the shape and size of the cross-section change at different parts of the beam. Hence, instead of having to consider the motion of each infinitesimal element of the beam, we may write down equations for the motion as a whole of the material contained between two adjacent cross-sections, and we may express these in terms of the relative displacements of the corresponding points of the centro-line. The number of independent variables is thus reduced from three (the co-ordinates of any point in space) to one (the distance of any section, measured along the centro-line, from a fixed point), and a great increase of simplicity in the calculations is thus obtainable.

For an account of the ways in which these principles are applied by engineers, in calculating the deflections which occur in girders under the action of lateral loads, reference may be made to the article on "Theory of Structures." Similar methods enable us to calculate the frequency with which a beam of given dimensions will vibrate, and the result thus obtained is of importance both in engineering design (where it is necessary to take precaution in advance against the dangers associated with "resonance"), and in the theory of sound. Corresponding simplification has been introduced into the calculations relating to thin plates or shells, and although such problems are necessarily of somewhat greater complexity, it is true to say that many problems can be solved by these approximate methods—with an accuracy which is quite adequate for practical purposes—which would be almost intractable by rigorous analysis. For the physical theory of sound, the late Lord Rayleigh's general treatment by approximate methods of problems relating to the vibration of elastic solids has proved particularly fruitful in results.

§ (14) Elastic Stability. One class of problem still requires notice. We have referred in § (6) to a theorem of Kirchhoff, that any solution of the equations of equilibrium which also satisfies the specified boundary conditions is unique. If we combine with this the assumption of Hooke's Law, that the strain varies proportionally with the stress, we may conclude that any strained configuration which we can determine will be stable, since departure from that configuration must of necessity be accompanied by an increase in the total potential energy of the system. But the theorem of Kirchhoff, being based upon the general equations (28) of motion or equilibrium, depends upon the implied assumption, that the strain which occurs in an elastic body, as the result of applied forces, does not affect appreciably the stress which these forces bring into existence at any point. This assumption is in general legitimate: but it fails in some instances when applied to elastic solids, such as thin rods or plates, of which the dimensions are widely different in different directions. For example, if we imagine a straight shaft, which initially rotates about its axis, to deflect into a curved form, then additional stresses will be called into existence as a result of that deflection, since the centripetal effect of rotation will tend to deflect the shaft still further.
ELASTICITY, THEORY OF

At some definite speed of revolution this distorting effect will exactly neutralize the deforming influence which the shaft possesses, in virtue of its elasticity, of reverting to the straight form, and hence the deflection, if it occurs, will be maintained. The equilibrium of the straight configuration has in fact become neutral, and the shaft is said to "whirl."

A similar tendency towards "elastic instability" is exhibited by a long straight rod, or "slender," which is subjected to axial compression. At a certain definite value of this end load, the equilibrium of the straight configuration becomes neutral, and the load can hold the strut bent into a curved form. Both of the examples here cited are of the first importance in engineering design, and the reader who desires to have further information about them should refer to the article on the "Theory of Structures."

Elastic instability can also occur in thin circular tubes, when these are subjected either to uniform compression or to hydrostatic pressure on their external surfaces (as occurs in practice in the fins of steam-boilers), or to torsion. It is then accompanied by the formation of waves, or corrugations, of very regular geometrical types, and the analysis, though difficult and lengthy as compared with that of the problems just described, is tractable and interesting, more particularly as regards the indications which it affords of precautions to be observed in practical work when structural members have to be built up from thin sheets of metal. The development of metal construction for aircraft has, in fact, given to this subject, which was formerly regarded as mainly of theoretical interest, a practical importance comparable with that of the more familiar problems of elastic theory.

§ 15 Photo-elasticity and Sonic-elastic Membranes.—Compared with other branches of mathematical physics, the subject of elasticity is remarkable for the extent to which theory has developed in advance of its experimental verification. Indeed, a little reflection shows that such verification is a matter of the greatest difficulty. No means have been devised for measuring the strains in the interior of an opaque body, and a comparison of the breaking loads given by theory and by experiment fails to supply the required verification of theory, for the reason that fracture in actual materials is preceded by a more or less lengthy period of transition from the elastic to the plastic state, during which the relations between stress and strain fail to obey Hooke's Law (cf. § 9).

The nearest approach to precise experimental verification which has yet been made employs the property of photo-elasticity. It is an experimental fact that an anisotropic transparent body—such as glass (which has the merit that it obeys Hooke's Law with considerable precision)—becomes doubly-refracting when stressed, its optical principal axes at any point being coincident with the directions of the principal axes of stress at the point; hence, by the aid of polarised light, it has been found possible to study many two-dimensional systems of stress which are not amenable to mathematical analysis.

In such systems, the stress-components are expressible in terms of a function \( \gamma \) determined by appropriate boundary conditions, and by the equation

\[
\frac{\partial^2 \gamma}{\partial x^2} + \frac{\partial^2 \gamma}{\partial y^2} = 0, \quad \text{(29)}
\]

which must be satisfied at every point of the \((x, y)\) plane lying within the elastic solid considered. In the solutions obtained by St. Venant for the stresses produced in a prismatic solid by tension or flexure (see § 11), the stress-components are found to be expressible in terms of a function \( \psi \) which satisfies the simpler equation

\[
\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0, \quad \text{(30)}
\]

Now equation (30) is satisfied by the normal displacements (when these are small) of an initially flat membrane which is subjected to equal tensions in all directions, and advantage has been taken of this fact by Taylor and Griffith, who have shown how to determine the function \( \psi \), for prisms of any given cross-section, by measurements made on a soap film stretched across a closed boundary of appropriate form. Such experiments are not, of course, to be regarded as a verification of elastic theory, but as a means of extending its results: they are typical of the present trend of its development, which tends more and more in the direction of practically useful extension, even at the cost of some slight decrease in accuracy.

References.—The standard work on the subject is Professor A. R. H. Love's Mathematical Theory of Elasticity, which in its third edition (Cambridge, 1929) includes references to practically every paper of importance in the subject which has so far been published. Most of the problems which have been applied successfully to practice are described in general, with diagrams which serve to show the order of magnitude of the stresses considered. In D. A. Moody's Strength of Materials, Sir J. A. Iddings' work of the same name, and other engineering treatises of similar scope. The following table of references, for individual paragraphs of the present paper, will serve as an acknowledgment of the use which has been made, in their preparation, of the works of Love and Moody.

Engines and Prime Movers:
THE BALANCING OF

§ (1) PRELIMINARY.—An engine is said to be balanced when it runs without vibration.

Masses are added to the moving parts to secure this immunity from vibration, and these masses are called Balance Weights.

The importance of keeping the engine still by balancing the moving parts lies in the fact that if it vibrates it communicates its vibration to the foundation on which it is mounted, and thus starts a wave which may spread to the surrounding buildings and cause trouble.

The trouble is very much increased if the foundation has a natural period of vibration equal to the periodic time of the vibration of the engine. Then the disturbance produced in the buildings is out of all proportion to the disturbance of the engine itself.

Synchronization of the engine vibrations, or of a harmonic of it, with the natural period of vibration of the foundation, or a harmonic of it, may thus cause troublesome or even dangerous disturbances in the buildings surrounding the station in which the engine is at work.

The balancing of marine engines when their speed was low and the period of vibration of the ship's hull high was not a pressing problem. But ships grew in size and engines increased in speed so that the natural period of vibration of the hull and the time of rotation of the engine approached synchronism and in some ships found it. Such ships were uncomfortable to travel in. Again the vibration produced by unbalanced engines in destroyers and cruisers was so noticeable that the designer speed in some ships had to be reduced because of the dangerous vibration produced.

The problem of balancing the engines so that they could work at any reasonable speed without producing vibration thus forced itself on the attention of engineers, and solutions exact, approximate, or roughly approximate, had to be found.

The necessity for balancing the moving parts of an engine arises from the manner in which those parts are compelled to move.

Change of speed or change of direction of a moving mass requires the action of an external accelerating force.

The moving parts of a machine are com.
The crank pin A is connected with the mass C by a rod AC, technically called the connecting rod.

However, the mechanism is not in motion; the path of every point in every link is defined. The distance OA is the crank radius. The distance C1C2 is the stroke of the reciprocating mass and is equal to 2OA. The end points C1 and C2 are called the outer and inner dead points respectively.

The mechanism furnishes three separate problems for consideration.

(1) The motion of a mass in a circular path at uniform speed.

(2) The motion of a mass in a straight path at varying speed.

(3) The motion of a link as defined by the motion of two of its points.

A. Motion of a Mass in a Circle at Uniform Speed.—Let M (Fig. 2) be the mass; R the radius of the circle in which the mass centre moves, and v the angular velocity of the mass about the centre of the circular path.

Then it is demonstrated in dynamics that the force necessary to cause the motion acts at the mass centre in a direction towards the centre of the circular path, and that its magnitude is equal to Mrω².

If M is reckoned in pounds the force is expressed in absolute units. If M is reckoned in gravitation units so that M = W/g, the force is expressed in lbs. weight, W being the weight in pounds.

The force acts at right angles to the direction of motion and has therefore no effect on the speed in the path.

This force can be automatically called into existence by connecting the mass to the centre of the path by a radial connection, OM (Fig. 3).

When the shaft is turned the mass must move in a circle described by the length of the connecting arm. The necessary constraining force is applied to the mass by the arm. An equal and opposite force is applied by the arm to the frame.

The force acting on the frame is constant in amount but varies in direction. At one instant it tends to lift the frame up, and next...
it acts to push it down. Placed on the platform of a suitable weighing machine the weight of the whole apparatus seen in Fig. 3 would appear to vary above and below its proper value by the small error in the lever.

For example, suppose the weight of the apparatus to be 100 pounds, of which the mass at the end of the arm, 1.5 foot radius, weighs 10 pounds. Then if the shaft were driven by an engine mounted on the apparatus at, say, 1 revolution per second, equal to 2π radians per second, the force in pounds acting on the frame would be 18.35 lbs.-weight.

The scale would therefore show a weight varying between 118.35 pounds and 81.65 pounds.

Increase the speed above that found from the relation $Ma^2R = 100$, and the upward force would be sufficient to lift the whole apparatus momentarily off the platform. For example, at 5 revolutions per second the force is 357 lbs.-weight, and under the action of this force the whole apparatus would jump up and down on the platform of the scale and produce a hammer blow.

This is in fact what may actually happen to the driving wheels of a locomotive if the revolving masses put in the wheel to balance forces in the line of stroke are massive enough and are driven at a high speed. This point is specifically considered in § (12) below.

The frame force (Fig. 3) may be entirely eliminated by the simple device of extending the radial connector as illustrated by dotted lines and connecting it to a mass equal to $M$ at the radius $R$. Then each mass provides the reaction to the other and the frame is not called upon for any reaction. The arm with its equal pair of masses may be driven at any speed without any tendency to produce vibration of the frame.

On the platform of a weighing machine the mass could be driven at any speed and no change of weight would be observed.

The tension in the connector rises and falls as the speed rises and falls.

The mass $M$ is said to be balanced by the mass $m$. It is not necessary that the balancing weight $m$ should be equal to $M$. The added mass has only to require a constraining force equal to the constraining force required by $M$. If a mass $m$ is added at radius $r$ to balance a mass $M$ at radius $R$, then equality between the constraining forces is secured when

$$Ma^2R = mra^2R$$

that is when $MR = mr$. (1)

This is the condition for the balancing of two masses on an arm and in the same plane.

It is customary to consider all masses as though they acted at a common radius. The radius usually selected is the CRANK RADIUS.

Reduction to crank radius is affected by equation (1).

(ii) Motion of a Mass in a Straight Line at Varying Speed.—Consider the revolving masses $C$ (Fig. 3). It is compelled to move in the straight path defined by the slide bar. Assume that the crank turns with constant angular velocity. Then the problem is to find what forces are required to produce the motion of the mass $C$ which is defined by the uniform turning of the crank.

The general method of finding the acceleration of $C$ is to form an expression giving the position of the mass in its path in terms of one independent variable. Then differentiate this expression twice with respect to the time. The result of the first differentiation gives the velocity of the mass in its path. The result of the second differentiation gives the acceleration of the mass in its path. The mass multiplied by the acceleration is then the force we are seeking.

The position of the mass $C$ (Fig. 4) is defined by the distance $x$. When the crank angle is $\theta$ the value of $x$ is

$$x = Ox + OC \cos \theta \div \sin \phi.$$  (2)

Eliminating $\phi$ by means of the relation $R \sin \phi = L \sin \theta$ and differentiating twice with regard to the time, remembering that $d^2\phi/dt^2$, the acceleration of the crank, is assumed to be zero, the acceleration of the mass is found to be

$$A = -\frac{R \cos \theta}{(L - R \sin^2 \theta)^2}.$$  (3)

The instantaneous value of the force in $\tau$ on the frame is $MA$ and the reaction on the frame is $-MA$.

The force is seen from this expression to vary in a complex manner. A way of producing exactly equal and opposite reaction on the frame to balance this is sketched in Fig. 5.

Fig. 5. A mass $C_1$ equal to the mass $C$ is made to slide by a constraining rod $A_1C_1$, equal in length to $AO$. For this arrangement to work there would be three cranks on the shaft: the central one $OA$, and two outer ones.
in the direction OA. The mass C would then be driven by two connecting rods, together equal in mass to the rod AC. The reciprocating masses of an engine constructed in this way would be in perfect balance.

In an actual engine the accelerating force is derived from the fluid pressure in the cylinder. The pressure on the piston has to produce the acceleration of the piston and rod and to transmit force to the crank pin through the connecting rod. The force therefore transmitted to the crank pin is the difference between the total force on the piston due to the steam pressure and that part of the force which has been employed in giving motion to the piston. After about the middle of the stroke, however, where the acceleration changes sign, the pressure on the crank pin is greater than that due to the total fluid pressure by the retarding force, which must be applied to the reciprocating masses by the crank pin.

The acceleration can be found graphically. Bennett's construction, given to the author by G. T. Bennett, D.Sc., of Emmanuel College, Cambridge, in 1892, is convenient for this purpose, and is as follows:

First (Fig. 6) find a point B on the connecting rod so that \(AB = BC = AO\). This point is found by drawing a perpendicular from O to the rod when the crank is at right angles with the line of stroke.

Then set out the mechanism with the crank at an angle \(\theta\). From B draw BS perpendicular to the rod. From S draw ST perpendicular to the line of stroke. From T draw TS perpendicular to the rod. Then IS represents the acceleration of the mass C in the scale on which AO represents the radial acceleration of the crank pin. The acceleration of C is therefore \(\frac{MB(BO - AO)}{AO}\) ft. per second per second.

The construction is exact and gives the same value for the acceleration as that which is calculated from equation (3). The proof of the construction is found from equation (1) by eliminating \(\phi\) instead of \(\theta\). It is given in Dalby's 'Balancing of Engines.'

The expression found in (3) is intractable. An approximation of great utility in practice is found by putting \(\cos \phi = -\frac{1}{2} \frac{2B}{5B}\) and \(\theta\) in the process of eliminating \(\phi\) from equation (2). The resulting expression for \(x\) differentiated twice then gives for the acceleration

\[
A = -c^2R \sin \theta - \frac{c}{12} \cos \theta \cdot \cos \theta
\]

As above an approximation to the true expression

\[
A = -c^2R \sin \theta - \frac{c}{12} \cos 2\theta
\]

as may be desired can be made by expressing \(A\) as a Fourier series. The general expression then becomes

\[
A = -c^2R (\cos \theta + A_1 \cos 2\theta - B_1 \cos 4\theta - \ldots) - \frac{c}{12} \cos 2\theta \ldots
\]

is which \(A_1, B_1, \ldots\) have the following values, the being the rule \(1/4t\),

\[
\begin{align*}
A_1 &= \frac{c^2}{4} \cdot \frac{15}{128} \\
B_1 &= \frac{c^2}{4} \cdot \frac{35}{112} \\
C_1 &= \frac{c^2}{128}
\end{align*}
\]

See also a paper by Mr. J. H. Macalpine in Engineering, Oct. 22, 1887.

(iii.) The Motion of the Connecting Rod (Fig. 7).

The end A, called the big end, is compelled to move in a circle. The end C, called the small end, is compelled to move in a straight line.

The dynamical problem is, assuming the rod to be fixed from its connections, what is the instantaneous force which must be applied to the rod to cause it to move the one end in a circle with uniform velocity, the other end in a line passing through the centre of this circle (Fig. 7).

The answer to this problem depends upon the mass of the rod and the way the mass is distributed, and on the speed.

There are two important mass points which must be treated before the solution can be found. These are the mass centre and the centre of percussion relative to the small end of the rod.

The mass centre is found by balancing the rod on a knife edge.

The centre of percussion II (Fig. 8) relative to the small end is found by suspend the rod so that it can oscillate about the small end, and then adjusting a plumb bob to oscillate in line with it. The length of the simple pendulum formed by the bob and its string is the distance from the small end to the centre of percussion required.

The following construction then gives the form corresponding to a given crank angle.
Draw the mechanism in the configuration corresponding to the given crank angle (Fig. 9).

Apply Bonnet's geometrical construction to find EO, the acceleration of the end C. Join BA.

EA is called the acceleration image of the rod. It has this property. Regarded as the connecting rod on a smaller scale, A being the big end and B the small end, the line joining any point on it to O represents in magnitude and direction the acceleration of the corresponding point on the actual rod. Let V be the mass centre, and H the centre of percussion of the rod about C. Draw Vr parallel to the line of stroke and join r to O; then rO is the magnitude and direction of the acceleration of the mass centre to the scale on which AO is the acceleration of the crank pin A.

The magnitude of the accelerating force is then

$$M_{AO} = AO$$

It remains to find its position.

Draw HP (Fig. 9) parallel to the line of stroke and join H to O. Through H draw a line parallel to Vr cutting the line of stroke in J. J is then a point in the line of action of the force. But its direction is given by Vr.

Therefore through J draw a line parallel to AO. This is the line of action of the force R, which is competent to produce the motion of the connecting rod at the instant the crank is passing through the angle θ. This force varies in magnitude and direction as the crank angle varies.

The force R is equivalent to an equal and parallel force R′ acting at the mass centre. The force R at the mass centre produces the angular motion of the rod, and the force R′ the linear or stroke motion of the rod. The combination of these motions produces the actual motion of the rod. The proofs of these propositions are given in detail in smelling.

The next step is to find the force F that can only be brought upon the rod by the slide bars. Therefore at G (Fig. 10) draw the line of stroke parallel to the line of stroke in S. Join S to A.

Then if ST represents a component S1, S2, S3, T1, T2, must be brought upon the rod by the slide bars. ST, the force which must be the big end by the crank components together the force of the rod.

The crank pin carries the crank shaft given D by the equal and parallel forces to the shafts of the crank shaft.

The couple modifies the frame on the crank.

The frame reactions are the lines in the figure.

The final result is the frame like that shown, acting through the same axes and causing vibration of the connecting rod exactly by the method.

In Fig. 8. With this result, the rods on the right are, to the rod on the left, the resultant of the forces R and F upon the motion of the rod is exactly equal and opposite of the forces on the frame the acceleration of the rod.

The forces were and were directions in exact neutralisation one another from the frame itself, accordingly produced by these forces, is the action of an unbalanced load has no tendency to vibrations.

In practice it is usual to effect the rod by means of its mass which is led, through its mass, and then the rod and the crank pin and the connecting rod the same centre of the mass.
balanced as part of the revolving masses; that assigned to the reciprocating masses is balanced with the reciprocating masses.

Considered as a system of two masses the frame forces produced are not exactly the same as the frame forces produced by the actual connecting rod, but while it is impossible to balance the rod except by another rod in the way shown, it is possible to balance these divided masses with ordinary balance weights with sufficient accuracy for most practical purposes.

§ (4) The Centrifugal Couple.—Referring to Fig. 3 it will be seen that the mass \( M \) is balanced by the mass \( m \) placed diametrically opposite to it.

Let Fig. 11 be the side view of a shaft carrying a mass \( M \) at radius \( R \), and for the moment suppose it to be supported on a pair of parallel knife edges at \( B_1 \) and \( B_2 \). If the balance weight \( m \) is placed opposite \( M \) at radius \( r \) such that \( M_1 = m_1 r \), but at a distance \( a \) along the shaft as shown in Fig. 11, and this is usually necessary in practice, it will still be found to balance \( M \) when the shaft is at rest. The shaft will stand in any angular position on the knife edges. It will be in perfect static balance if now the shaft is put in bearings, say, at \( B_1 \) and \( B_2 \), its revolution will set up vibrations.

Although it is in static balance it is not in running balance. The disturbance is now produced by the couple formed by the reaction of \( M \) on the shaft, giving a force \( M_1 r \), and by the equal and opposite reaction \( m_1 r \) on the shaft, these two reactions being separated by the distance \( a \). This couple tends to turn the system about an axis perpendicular to the plane containing the forces.

The distance \( A \) between the forces is called the Arm of the couple, and the product of one force into the arm is called the Moment of the couple.

The couple is called the centrifugal couple, because its forces are the centrifugal forces caused by the rotation of masses.

A couple can only be balanced by an equal and opposite couple acting in its plane. That is, the four forces of the pair of couples lie in one plane, and this plane contains the axis of the shaft.

The moment of the centrifugal couple caused by the mass \( M \) and its balancing mass \( m \) is \( M_1 r \).

It may be balanced by a couple \( M_1 r = M_1 r \), the quantities being taken so that

\[ M_1 r = M_1 r \]  \( \text{(1)} \)

These couples must act so that they tend to produce rotation in opposite directions.

The dotted lines in Fig. 11 show a balancing couple. If masses, radii, and the arm \( B \) satisfy the equation above, and if in addition \( M_1 R_1 = m_1 r_1 \) and \( M_2 R_2 = m_2 r_2 \), then it will be seen that the shaft may be driven at any speed and there will be no vibration.

At the same time the shaft will stand in any angular position on the knife edges. The masses disposed round it satisfy in fact two separate conditions.

They are in static balance, and they are also in running balance. Static balance implies that the mass centre of all the masses lies on the axis of revolution of the shaft.

Running balance implies that the centrifugal couples of all the masses form a system in equilibrium.

§ (4) The Practical Problem.—The problem of balancing an engine presents itself in practice in this way. An engine is designed to fulfil conditions of power, speed, and arrangement, and the result is a crank shaft driven from a number of cylinders. Usually the lines of stroke of the cylinders are contained in one plane, and this plane contains the axis of the crank shaft. If there are \( n \) cylinders, then there are \( n \) piston masses, \( n \) cranks, and therefore \( n \) revolving masses, and also \( n \) connecting rods. The accelerations of each of these systems of \( n \) masses cause frame reactions.

As mentioned above, the connecting rod is eliminated from the problem by distributing its mass between the revolving and the piston masses.

There are now two balancing problems:

(1) To balance the revolving crank shaft masses.

(2) To balance the reciprocating piston masses.

Both fall under one method of solution.

§ (5) Solution of the Balancing Problem.—The initial problem to be solved may...
be stated in this way. Given a revolving shaft with a number of masses attached to it, find the balance weights which must be added to secure static and running balance.

Solution.—Select a plane at right angles to the shaft in which it is intended to attach one of the balance weights. This plane is called specifically the Reference Plane.

The reference plane may be regarded as a definite plane like a drawing-board, keyed to and revolving with the shaft.

Transfer each centrifugal force \( M_o^2 R \) in turn to this plane. Each force transferred gives rise to

1. an equal and parallel force, \( M_o^2 R = F \), acting in the plane;
2. a couple \( Pa \), where \( a \) is the distance through which the force is transferred.

The transference of one force to the reference plane is illustrated in Fig. 12. Here the rotation of the mass \( M \) produces the centrifugal force \( M_o^2 R = F \) on the shaft, and this transferred to the reference plane gives the equal and parallel force \( F \) and the couple \( Pa \).

For, introduce two equal and opposite forces \( F \) at the point \( O \) in the reference plane. Then these forces being in equilibrium themselves do not affect the equilibrium of the system. The three forces, \( F \) from the mass \( M \) and \(- F \) introduced at \( O \), may then be analyzed into the equal and parallel force \( F \) acting at \( O \) in the reference plane and the couple \( Pa \).

Draw a line \( OA \) parallel to the radius to \( M \) to represent the couple \( Pa \). Its length \( OA \) is chosen so that \( OA = Pr \) and its sense is marked off according to the direction in which the couple tends to turn the shaft about \( O \).

That is, its sense will be from \( O \) outwards in the radial direction of the mass for all masses on the right of the reference plane, and from \( O \) in the direction opposite to the radial direction of the mass for all masses to the left of the reference plane.

Also draw \( OB \) to represent the force.

Then every mass \( M \) revolving with the shaft will give rise to two vectors in the reference plane, a force vector like \( OB \) pointing always in the radial direction of the mass, and a couple vector \( OA \) pointing in the radial direction settled as above.

The next step is to find the resultant of the couples. For this purpose set the couple vectors out in any order to form a polygon. If the polygon closes, then there is no unbalanced couple. If it does not close, the vector required to close it is given in magnitude sense and direction the couple required to balance the couples about \( O \).

The couple closure, as this line is called, is the product of four quantities, namely, \( R \), an unknown mass \( M \) acting at a convenient radius \( R \) from the shaft and in a plane at a convenient distance \( d \) from the reference plane, and is equal to \( M R d a \).

Select a plane at a distance \( d \) from the reference plane where a balance weight may be conveniently introduced. Select a radius \( R \) at which it is convenient to place the balance weight in this plane.

Finally calculate the magnitude of the balance weight from the equation

\[
\text{Couple closure } \frac{M}{d} = \frac{R a}{d}.
\]

The angle at which the radius stands in relation to the other radii on the shaft is given by the direction of the closure line in the polygon.

Then add this balance weight to the system, and transfer it to the reference plane as before, thus adding one more force to the system already there. The couples now balance.

Then set out the force vectors in any order to form a polygon. If this force polygon closes, then there is no unbalanced force. If it does not close, the vector required to close it is given in magnitude sense and direction the force required to balance the forces acting at \( O \).

The force closure is the product of three quantities, namely, a mass, a radius, and \( \omega^2 \).

Select a radius at which it is convenient to place the balance weight in the reference plane, and then calculate its magnitude from the equation

\[
\text{Mass } = \frac{\text{Force closure}}{\omega^2}.
\]

The angle of the radius to the balance weight is given by the direction of the closure in the polygon.

\( \omega^2 \), being constant for all masses, may have any value in working out the solution. Therefore call it nilly.

The addition of the balance weight in the reference plane to balance the forces there has no effect on the balance already produced.
between the couple. Because a force acting at O has no moment about O, and can therefore be added or removed without introducing a couple into the system.

This is the essence of the solution. The couples are balanced first, and then the forces are balanced without disturbing the balance between the couples.

It is easily shown that if the forces and the couples are separately balanced about any one point along the shaft they are separately balanced about every point along the shaft. Therefore, after the balance weights have been found by the method explained, and have been added to the system, it will be found that both the couple and the force polygons will close for any position of the reference plane along the shaft.

The balance weights found are independent of the position chosen for a reference plane.

This property enables the work to be checked.

Having found the balance weights as described, include them in the system, and then select a reference plane at a new place along the shaft.

Ignoring the knowledge that the system is balanced, proceed to find balance weights. It should be found that both force and couple polygon close, showing that no balance weights are required. If the polygons do not close, there has been some error in the original determination of the balance weights. This error should be corrected.

A check on the accuracy of the work is a valuable element of the Daily Solution.

§ (6) Example.—Let there be three masses—M = 17 pounds, M = 16 pounds, and M = 7 pounds—attached a common radius R to the shaft. SS (Fig. 13) spaced along the shaft as shown, and spaced angularly around the shaft as defined in the end view of the shaft (Fig. 13).

The mass centre of each mass revolves in a plane to which the shaft is perpendicular.

Let the problem be to balance these three masses by two balance weights, the one being placed in the plane No. 1, and the other in the plane No. 5.

Choose the reference plane to coincide with the plane of revolution of one of the balance weights.

We may therefore choose either plane No. 1 or plane No. 5. Let us choose plane No. 1. Then we draw the diagram showing the distance of each plane in which a mass revolves from the reference plane in the manner indicated in the figure.

Arrange the data in the way shown in Table 1.

Next, set out the couple vectors of column 4 in the way shown in Fig. 14. Choosing any convenient scale, draw A'B = 51 and parallel to radius 2 (end view, Fig. 13). BC=136 and parallel to radius 3. CD = 84 and parallel to radius 4. DA the closure, measuring 83, is the couple required to produce balance amongst the couples.

The balance weight in plane 5 is calculated from (Rw2=1).

Couple closure = 83

The angular position of the radius of this balance weight is defined in relation to the others by drawing radius 5 in the end view parallel to the closure of the couple polygon.
This mass is now entered in the schedule as indicated. There are now four forces acting at O in the
reference plane. Starting from any origin, set out (Fig. 16)

\[ ab = 17 \parallel \text{radius } 2 \text{ (and view, Fig. 13)} \]
\[ bc = 10 \parallel \text{radius } 3 \]
\[ cd = 7 \parallel \text{radius } 4 \]
\[ de = 11.0 \parallel \text{radius } 5 \]

en, the closure measuring 14\(^{\circ}\), is the balance weight at common radius required to balance the forces at O. The angular position of the radius of this balance weight is defined in relation to the others by drawing radius 1 in the end view parallel to the closure of the force polygon.

These two balance weights added to the system in the plane specified, and in the angular positions defined in the end view, produce a system of five masses in both static and running balance. The shaft can be driven at any speed when held in a pair of bearings placed anywhere along the shaft without producing vibration of the supports.

Whatever value is given to \( w \) it will be the same for each mass, and therefore will not make any difference in the balance weights found.

§ (7) Deductions from the Force and Couple Polygons.—The balance of a system of revolving masses may be tested by selecting a reference plane or at any point along the shaft and then following the method above. Unless the plane has been selected to coincide with one of the planes in which a mass revolves there will be in the reference plane, after the transformation of the forces to it, a couple vector, and a force vector. If the masses are in balance the couple vector set out in any order will form a closed polygon of \( n \) sides; and the force vectors set out in any order will form a closed polygon of \( n \) sides. Corresponding sides of these two polygons are parallel, but the ratio of the lengths of a pair of parallel sides is different for each pair. The ratio of a pair is in fact the distance \( a \) from the reference plane of the mass whose force and couple are respectively represented by the pair of parallel sides.

The balancing of a mass amongst themselves is thus conditioned by those geometrical properties of the force polygon and the couple polygon.

If, when the vectors are set out, it should be found that the force polygon closes, but the couple polygon does not close, then the masses are in static balance, but are not in running balance. There is no unbalanced force, but there is an unbalanced couple causing reactions on the frame.

A few important practical limitations can at once be deduced from these polygons.

(a) Three masses carried on three arms spaced along a shaft can only mutually balance if the arms are in one plane, in plane containing the axis of the shaft. Seen in end view the arms would all lie in a diameter.

For it is only possible to draw two polygons of three sides each, with corresponding sides parallel, and the ratio of the lengths of each parallel pair different, if the polygons close into a line. It follows that the arms carrying the masses must be in a line so that the middle arm is at \( 120^\circ \) with the two outer arms.

Therefore a crank shaft with three cranks at \( 120^\circ \) cannot be designed so that the masses mutually balance. If the masses were equal, the force polygon closes and static balance is obtained. But in these conditions the couple polygon cannot be closed.

To balance three masses set at angles with one another a fourth mass must be added to the system equivalent to a fourth crank. The system is then equivalent to four masses on four cranks.

(b) Four masses on four arms spaced along a shaft can in general be balanced amongst themselves, because a pair of polygons can be found in which corresponding sides are parallel, and in which the ratio of the lengths of each parallel pair is different.

(c) But four masses spaced along a shaft on four arms set at \( 90^\circ \) with each other cannot be designed to balance. If the four masses are equal the force polygon closes, and there is static balance. But with the angles all right angles the couple polygon cannot be made to close.

Therefore a crank shaft with four cranks
not at 90° with each other cannot be designed so that the masses balance. Balance can only be obtained by adding a fifth mass to the system equivalent to a fifth crank. The system is then equivalent to five masses on five cranks, but with the condition that four of the cranks are mutually at right angles.

Many other useful conditions can be deduced from the geometric properties of the force and couple polygons.

§ (8) The Balancing of a Rotor—The rotor of a steam turbine is truly turned, and the balancing is symmetrical. At first sight it would appear that there is here no balancing problem, because so far as constructional skill can go the mass centre of each elementary disc, of which the length may be imagined to be made up, lies in the axis of rotation. But owing to slight variations in density, and in the symmetry of the blade, the mass centre of each elementary disc is in general slightly displaced from the axis of rotation. Although these displacements are slight the speed at which the rotor is driven involves accelerating forces which are large enough to cause vibration. So that, after all, there is a rotor balancing problem, and a difficult one, because the displacements of the mass centres of the elementary discs cannot be identified by any method of weighing or measurement.

The problem is in fact similar to that which would be presented to a designer asked to work out the balance weights for a totally enclosed reciprocating engine, with access to the parts denied. All he would see of the moving parts would be the ends of the crank shaft projecting through the bearing at each end, and all he would know of them would be that their motion produces vibration.

Similarly, all he can see in a rotor is an apparently truly turned mass, symmetrically bladed, and all he knows of it is that when driven it produces vibration.

He might by imagination conceive the rotor to be made up of a series of elementary discs, but the position of the mass centre of each disc would be hidden from him without possibility of discovery.

Mr. King Salter, in a paper to the Institution of Naval Architects read at the spring meeting of 1920, has described an ingenious method of solving the problem.

The rotor to be balanced is placed in bearings and is driven by a motor. Being unbalanced it produces a reaction on each bearing. These reactions are separately measured in the horizontal direction. Let \( R_1 \) and \( R_2 \) be the respective maximum reactions measured in the apparatus when the rotor is driven at \( \omega \) revolutions per second. Then each reaction may be regarded as produced by a mass \( M \) attached to the rotor at radius \( r \). So that the maximum horizontal reaction at each bearing is expressed by

\[
R_1 = M \omega^2 r_1, \quad (1)
\]

\[
R_2 = M \omega^2 r_2, \quad (2)
\]

from which

\[
M_1 = \frac{R_1}{\omega^2 r_1}, \quad (3)
\]

\[
M_2 = \frac{R_2}{\omega^2 r_2}, \quad (4)
\]

\( M_1 \) and \( M_2 \) can be calculated from (3) and (4) because \( \omega^2 \) is observed, and \( r \) may be put equal to unity or to any convenient constant length.

The next part of the problem is to find the angular position of the radii \( r_1 \) and \( r_2 \). This is done by the apparatus described in the paper.

The rotor, with its hidden system of unbalanced masses, may now be replaced by a shaft with two known masses attached to it at known angular spacing as illustrated in Fig. 17. Fig. 16 shows the rotor and the centres of the bearings at which the reactions are measured. Fig. 17 shows the equivalent unbalanced system of two masses as determined in Mr. King Salter's apparatus. The two planes in which balancing masses are to be placed are now fixed upon. One is chosen as a reference plane, and then the solution of § (8) is applied to find the actual magnitude and position of the balancing masses to be placed in the two respective planes.

The arrangement is shown in Fig. 18.

The usual shop method of balancing a rotor is to place it on a pair of level and parallel knife edges and then add balance weights until it will stand in any angular position on those knife edges. This process ensures static balance but not running balance. The unknown unbalanced couple cannot be calculated from experiments on parallel knife edges,
and in practice the proper distribution of balancing masses to secure running balance is done by trial and error. After static balance is secured the rotor is driven up to speed, and if the couple is sufficient to produce disturbance the weights added to secure static balance are distributed so that the running balance is improved without interfering with the static balance. Considerable experience is required to get this done satisfactorily. It is advisable to test the balance of a turbine rotor in steam so that the rotor and its blades have expanded to the positions they occupy at the normal running temperature.

A full description of Mr. King Salter’s apparatus will be found in the paper cited above. Briefly it consists of a substantial bed with a bearing at each end. Each bearing can slide horizontally through a limited distance, but is prevented from doing so by a spring screwed up against it. When a trial of a rotor is being made the spring is compressed against the bearing so that it just prevents it moving. The strength of the spring is known, so that the maximum force acting horizontally on the bearing in the direction of motion can be observed. On each end of the rotor is placed a spider or flange, carrying on its periphery a number of radial spokes like the spokes on a steering wheel, but with this difference, that they are free to slide towards radially, but once pushed in they cannot come back. When the spokes have been keyed on the end of the rotor, all spokes are set to the limit allowed, the rotor is driven at the testing speed by an independent motor, and the rotor is then discontinued. The bearings are then slightly released so that the rotor can move horizontally under the unbalanced forces. A kind of brake shoe is then gradually approached to the spokes and pushed on to them until the ends are running in a circle. The rotor is then brought to rest, and an examination of the spokes shows the particular radius corresponding to the maximum horizontal displacement, and therefore in the maximum values of the forces on the corresponding bearing.

The displacement of the mass centre of a rotor and the angular position of the plane containing the mass centre and the axis of the rotor can be found by direct weighing in the Martin rotor balancing apparatus. The method and the apparatus are described in Engineering, December 31, 1920. By the aid of this apparatus a static balance of great accuracy can be obtained. For many rotors static balance may be sufficient, as for the thin disc-like rotors of girostats. If the static balancing of a rotor is found to be insufficient, its dynamical balance can be tested and secured by the aid of Mr. King Salter’s apparatus.

§ 9 (b) Four Masses, Special Construction.

Four masses may be set together in mutual balance in an infinite variety of ways. For an infinite number of pairs of four-sided force polygons can be drawn at random in geometrical conditions mentioned of its sides the relative magnitudes of the masses, and by the directions of its sides the positions of the cranks.

Thus in the end view draw crank Ss parallel to the side OA; Ss parallel to the side AB; Ss parallel to the side CB, and So parallel to the side OB.

If now the system be tested it will be found that the couple polygon is closed. The proof of this will be found in Daly’s Engineering, 2nd edition, 1868, p. 138.

The constructional model may be varied in many ways. For example, the angular position of the cranks in end view may be drawn at random. Then select any pole O and draw lines radiating from it parallel to the crank directions. Then draw across the sligo line SS, and the intersections define the position along the shaft.

Then draw a line as AB parallel to the line SS and finish the force polygon. This gives then define the magnitude of the masses.

§ 10 The Balancing of Reciprocating Masses.—We have now to consider the balancing of the reciprocating masses of a multi-cylinder engine of the type where the center lines of the cylinders lie in a plane containing the axis of the crank shaft.

In the marine type the plane is vertical. In the ordinary land type the plane is usually horizontal, though often vertical. In the V engine the plane is inclined, and these are
tions of a mass $M$ by a crank turning with uniform velocity is given by equation (3), § 2.

A way of producing an exact equal and opposite reaction on the frame is described and illustrated in Fig. 5.

This construction is, however, excluded from the problem before us.

An expression giving values close to the values from (3), and derived from equation (4), § 2, is

$$P = M a \cos \theta + M(2a)^2 \frac{R^2}{4L} \cos 20\theta$$ (1)

The first term of this expression is the projection on the line of stroke of the centrifugal force due to the rotation of the mass $M$ at radius $R$ and at speed $\omega$.

The second term is the projection on the line of stroke of the centrifugal force due to the rotation of a mass $M$ at radius $\frac{R^2}{4L}$ and at speed $\omega$.

The greater the length of the connecting rod in relation to the crank radius the smaller the second term.

In the limit, when the rod is infinitely long, the second term vanishes. The crank and slotted bar mechanism partly realises this condition. The ratio of rod to crank is often large enough to make this second term negligibly small. In locomotives the ratio of rod to crank may be 7 to 1, and even more. But in some kinds of marine engines it may be only 3 to 1.

The second term then becomes important.

When the second term is ignored in the balancing the engine is said to be balanced for primary forces and primary couples only.

If, however, the second term is included in the problem, the engine is said to be balanced for primary and secondary forces and couples.

(i.) Primary Balancing. — Since the term $MaR \cos \theta$ is the projection on the line of stroke of the centrifugal force produced by the rotation of a mass $M$, the conditions of primary balance amongst $n$ reciprocating masses are the same as those for a revolving mass, and may be investigated by assuming that each mass is attached to its own crank pin, so that the $n$ reciprocating masses are replaced by $n$ revolving masses. For if a polygon is closed, then the projections of the sides on any line are algebraically equal to zero. In other words, if the conditions of balance for the revolving masses are satisfied, so too are the conditions for the equivalent reciprocating masses. The Dalby Solution of § 5 may then be applied without change to find the balance weights of the substituted revolving system, and the balance weights found reciprocated in the cylinder plane will balance the reciprocating masses.

The example of § 6 may be restated thus. The reciprocating masses of a three-cylinder vertical engine weigh respectively $M_1 = 17$ pounds, $M_2 = 15$ pounds, $M_3 = 7$ pounds. These masses are reciprocated by cranks spaced along and around the crank shaft, as defined by Fig. 19. Find the reciprocating balance weights. The answer is (see Schedule 1) 14-4 pounds reciprocated by crank No. 1; 11-0 pounds reciprocated by crank No. 5; the lines of reciprocation lying in the plane containing the centre lines of the cylinders.

The masses may be designed as lumps of metal reciprocated in properly lubricated guides on the engine frame. They would then be called Bon Weights. The engine would be described as a three-cylinder engine in which the reciprocating masses, that is the piston masses, were balanced by a pair of bob weights.

Each balance weight may, however, be designed into a set of piston masses and added complete with cylinder and valve gear to the engine. Then the engine would be described as a five-cylinder engine with the piston masses in balance amongst themselves.

The problem of balancing an engine, as stated in § 4, involves the separate solution of two problems. First find the reciprocating balance weights, and add them to the engine either as bob weights or as pistons. Secondly find the balance weights for the revolving system of the crank shaft and add them to the crank shaft.

Each of these problems is separately solved by the application of the method given in § 5.

The deductions of § 7 apply equally to systems of reciprocating masses. It follows that the fewest number of cylinders in which the pistons may be set in mutual balance is four.

Much has been written about the balancing of four-cylinder engines. In practice, however, even for primary balancing, the valve gear must often be included to get the best results: In particular a four-cylinder torpedo-boat engine becomes with its valve gear a problem in balancing twelve lines of parts. There are no subsidiary problems involved in the complete solution, for which see the work-out example in Dalby's Balance of Engines.

(ii.) Secondary Balancing. — Since the second term of equation (1) above gives a force which is the projection on the line of stroke of a mass $M$ revolving at twice the speed of the main crank at radius $\frac{R^2}{4L}$, the condition that the secondary forces shall balance is that the corresponding force and couple polygons shall close. A schedule is made, as illustrated in Schedule 1, and the work is carried out as in § 6, but with this difference, the end view of the shaft must now show all the crank angles doubled.

Balancing to satisfy the conditions of equation (1) is therefore conditioned by the closing of four polygons, namely, a primary force

polygon, a primary couple polygon, a secondary force polygon, and a secondary couple polygon.

Given an engine, there is no difficulty in applying §(15) to test the primary and secondary balance, but it is more convenient to deduce the relations conditions analytically.

The following method affords a solution. 1

The direction of a crank measured from a fixed line is defined by the expression \( x_t + iy_t \), where \( t = \sqrt{-1} \). \( x_t \) is measured along the fixed direction, \( y_t \) is measured at right angles to it. Also \( x_t^2 + y_t^2 = 1 \).

The direction of a crank corresponding to this, starting in coincidence along the fixed direction and revolving twice as fast, is given by

\[
x_t^2 - y_t^2 + 2x_t y_t = 0
\]

If \( M_1 \) is the mass at radius \( R_1 \), the corresponding force and couple reactions are

**Primary force**

\[M_1 x_t R_1 (x_t + iy_t) \]

(2)

**Primary couple**

\[M_1 y_t R_1 (x_t + iy_t) \]

(3)

**Secondary force**

\[M_2 x_t^2 R_2 + \frac{L}{2} (x_t^2 - y_t^2 + 2x_t y_t) \]

(4)

**Secondary couple**

\[M_2 y_t^2 R_2 + \frac{L}{2} (x_t^2 - y_t^2 + 2x_t y_t) \]

(5)

Fig. 20 shows the relations of these quantities for one mass \( M_2 \).

For every reciprocating mass there is a set of terms corresponding to these four expressions. The condition that the masses may balance is expressed by the eight simultaneous equations:

**Primary forces vanish**

\[(M_1 x_t + M_2 x_t + \ldots) = 0\]

\[(M_1 y_t + M_2 y_t + \ldots) = 0\]

**Primary couple vanish**

\[(M_1 x_t + M_2 x_t + \ldots) = 0\]

\[(M_1 y_t + M_2 y_t + \ldots) = 0\]

**Secondary forces vanish**

\[(M_2 (x_t^2 - y_t^2) + M_2 (x_t^2 - y_t^2) + \ldots) = 0\]

\[(M_2 x_t y_t + M_2 x_t y_t + \ldots) = 0\]

**Secondary couple vanish**

\[(M_2 (x_t^2 - y_t^2) + M_2 (x_t^2 - y_t^2) + \ldots) = 0\]

\[(M_2 x_t y_t + M_2 x_t y_t + \ldots) = 0\]

by "On the Balancing of the Reciprocating Engine, placing the Effect of the Connect, 1" Transactions of the Institution of Naval 3, 1891.

With the general relation \( x_t^2 + y_t^2 = 1 \) for all \( x_t \) and \( y_t \) with the same subscript.

Each of these eight equations has one term for each reciprocating mass.

It is not possible to find a solution of any practical value with fewer than 5 lines of parts, that is, with 5 terms in each line. The engine could be built either as a five-cylinder engine or a three-cylinder engine with a pair of side weights.

The exploration of the possibilities of balance with engines of different numbers of cranks will be found in the four cited above.

§ (11) THE YAWING SCHLICK TWENTY MARINE ENGINE.—This is a four-cylinder engine with reciprocating parts balanced amongst themselves for primary forces and primary couples.

Later a four-cylinder symmetrically arranged engine with the reciprocating parts balanced amongst themselves for primary and secondary forces and for primary couples was used, and the method of getting this balance was described in a paper at the Naval Architects in 1000 by Schlink.

Although the eight fundamental equations of the preceding section cannot be simultaneously satisfied for an engine giving only four terms in each equation, yet it is possible to satisfy the first six of them with four terms of each. Thus a four-crank engine can be set to satisfy the first six equations, and thus it can be designed for primary and secondary balance of the reciprocating forces and primary balance of the couples, but the secondary couples must remain unbalanced.

The symmetrical engine is indicated in Fig. 21. A reference plane is taken at the center of the shaft and the cranks are spaced so that \( a_1 = -a_2 \). The angle 103 is made equal to the angle 204, and the mass \( M_1 \) is taken equal to the mass \( M_2 \). With these assumptions, the first six equations give

\[ M_1 = M_2 \quad \text{and} \quad a_1 = -a_2 \]

and further

\[ a_2 a_3 = -\frac{1}{3} \]  

(1)

\[ a_1 a_4 = -\frac{1}{2} \]  

(2)

where \( \frac{d}{2} = \frac{a_1^2}{a_3^2} \) and \( \frac{d}{2} = \frac{a_1^2}{a_4^2} \)

and

\[ M_2 = \frac{2a_1}{2a_3} \]  

(3)

When the spacings \( a_1 \) and \( a_2 \) are given, \( a_2 \) is calculated from (2), and then \( a_1 \) from (1), and the ratio of the reciprocating masses from (3).
The solution of the first six equations with four terms each is not limited to the symmetrical engine.

The expressions for unsymmetrical engines are complicated. The general solution is given by Lebreton in *Dynamique des Machines à Vapeur* (Paris, 1861), and Professor Engelse, in a paper printed in the Transactions of the Institution of Naval Architects, gives curves from which the graphical solution can be found for the proper given conditions.

It will be remembered that in the special construction given in § 8 (9) for the four-crank engine the polar arm is absent at random. The quantities then satisfy the first four of the eight equations. There is one position of the pole and one only which yields results which satisfy the last six equations. Schück, in the paper mentioned above, gives a geometrical construction for finding this position for the symmetrical engine. See the study of the problem by G. T. Bennett in a paper entitled "The Balancing of the Four-Crank Engine," read before the International Congress of Mathematicians at Cambridge, August 1812; also a paper by Professor Engelse, *Trans., Inst. Naval Arch.,* 141, Part 1.

The setting of the four main cranks derived from these six equations and the resulting four reciprocating masses produces balance only amongst themselves. The valve gear with its heavy reciprocating valve has received no consideration. In practice the valve gear must be brought into the problem to secure the best results. A compromise can be made which results in perfect primary balance for forces and couples of all the reciprocating parts, including the pistons and the valves, whilst the condition for secondary balance of the forces is nearly satisfied.

§ 12. The Balance of Locomotives.*

Each coupling rod is imagined to be replaced by masses concentrated at the crank pins. The pin shows the mass of a rod in the proportion in which they share its weight. Then by § (5) may be found the angular positions and the masses at crank culastio to balance the revolving masses of each axle. A balance weight is usually cast with the wheel and is often shaped in the form of a crescent. Let us have the masses of the crescent-shaped balance weight, excluding the mass of the spokes passing through it, and let $r$ be the radius of the mass center, then by trial and error values of $a$ and $r$ must be found such that $m = MR,$ where $M$ is the balancing mass at crank radius $R.$

The reciprocating masses are usually balanced by revolving masses placed in the driving wheels. These are combined with the masses required to balance the revolving parts, so that the balance weight seen in a driving wheel is the resultant of two balance weights, namely, one to balance the revolving masses, the other to balance the reciprocating masses. The balance weights added to balance the reciprocating masses are themselves unbalanced in the vertical direction and so produce a varying pressure on the rails. Let $W$ be the static load on a driving wheel, that is, the load measured on a weighbridge, and let $W$ be the revolving mass at radius $r$ added to balance the reciprocating masses, then the static load is alternately increased and diminished per revolution by the amount $W r^2$ pounds. Suppose it here the angular velocity of the wheel in radians per second. It is more convenient to express the angular velocity in terms of the speed of the engine. Let $V$ be the speed of the engine in miles per hour, and $D$ the diameter of the wheels in feet, then the maximum and minimum load on the rail can be calculated from

$$W = \frac{0.000122mV^2}{D^2} \text{ (tons).}$$

An average type of coupled engine would have $W = \frac{7}{8}$ tons on the driving wheel, and if the reciprocating parts were fully balanced the second term may reach the value of 3 tons at 80 miles per hour even on a wheel as large as 7 feet diameter.

The rail load would then vary between 12½ tons and 3½ tons per revolution. This would be destructive to the permanent way, especially to the cross orders of bridges, but the tractive pull would be even. It is better from the permanent way point of view to leave the reciprocating masses unbalanced. But if this is done the 1-ton variation appears on the tractive pull. In practice a compromise is made and it is usual to balance only ½ of the reciprocating masses, leaving ½ to vary the tractive pull and throwing the effect at ½ on the permanent way.

Having decided what proportion of the reciprocating masses is to be balanced, proportionate masses are supposed concentrated on their respective crank pins. And since the balance weights are going to be added, not as reciprocating masses but as revolving masses, these masses can be included in the analysis of the revolving masses, and § (5) applied to find straight away the resultant balance weights for the driving axle.

When the driving wheel is small there may be difficulty in designing a suitable balance weight for it. The revolving balance weight added to balance the reciprocating masses may then be distributed between the coupled wheels equally or in any proportion thought suitable. The balance weight then seen in any one of the coupled wheels is the resultant of the balance weight required to balance the revolving masses, and the balance weight required to balance the proportion of the reciprocating mass transferred to it.

This distribution of the balance weight required to balance the reciprocating masses also distributes the hammer blow on the
variation of rail load is called. For example, the hammer blow of 4 tons under the driving wheel may be distributed to give 1.5 tons under each of three coupled wheels.

The reciprocating masses of a four-cylinder locomotive may be balanced amongst themselves, as explained in § (10). The possibility is, however, taken advantage of because the cranks are generally arranged in two 180° pairs at right angles.

It has been pointed out in § (7) (c) that this is the angular spacing at which mutual balance is impossible. If the reciprocating masses are equal there is balance for the forces but the couple is unbalanced. This means that the reciprocating masses produce no variation of the tractive pull, neither is there any variation of road pressure, so that there is no hammer blow. But the unbalanced couple acts on the engine to make it sway laterally. This swaying can be corrected by the addition of revolving masses in the driving wheel, but these masses, although without effect on the tractive pull, introduce a hammer blow.

If the angles and masses were designed to secure balance there would be no variation of tractive pull, no hammer blow, and no swaying couple. Four sets of valve gear would be required as against the two sets with which the four-cylinder locomotive is usually operated.

§ (13) BALANCING OF INTERNAL COMBUSTION ENGINES.—The petrol engine, which has been used mainly to drive motor cars, has been developed during the war into a powerful prime mover for aircraft. Dynamically aircraft engines can be distinguished into three types:

Type A. An engine with its cylinders ranged in a line along the crank shaft so that the cylinder centre lines and the crank shaft axis lie in a plane.

Type B. The V engine formed by placing engines of type A to drive a common crank shaft and arranged about it so that the planes containing the centre lines of their cylinders intersect in the axis of the common crank shaft. Thus two four-cylinder engines of type A become an eight-cylinder V engine driving a four-crank shaft. Three four-cylinder engines of type A become a double V engine of twelve cylinders driving a four-crank shaft.

Type C. The radial engine in which the cylinder centre lines radiate from the centre of the crank shaft and all lie in a plane perpendicular to the axis of the crank shaft.

Petrol Engine, the Water-cooled"; "Air-planes," Vol. IV.

Internal combustion engines used in submarines, in factories, and in motor cars belong as a rule to class A.

The balancing of engines of type A has been considered in sections (5), (41) and (7); and from the results there given, deductions can be drawn for few arrangements found in internal combustion engines, but not yet specifically considered.

The four-crank engine of type A with equal reciprocating masses and with cranks set, the middle pair parallel and at 180° with the middle pair, and with the cranks symmetrically pitched along the crank shaft, is the usual arrangement found in a four-crank motor car engine. With these conditions the reciprocating masses are balanced for primary forces, for primary, secondary, and all higher orders of couples, but are unbalanced for secondary forces.

The unbalanced secondary force may be shown to be

\[ \frac{4M_2 a^2}{l^2} \cos 2\theta \text{ lbs.-wt.} \]

acting vertically at the centre of the crank shaft.

\( M \) is the mass in pounds of one set of reciprocating parts, \( a \) is the crank radius in feet, \( l \) is the length of the connecting rod in feet, and \( \omega \) is the angular velocity in radians per second. This reduces to very nearly \((5M_2 a^2/l)\cos 2\theta\) for \( \omega = 32.2 \) radians per second.

An eight-cylinder V engine formed by setting two four-cylinder engines of the above kind together at an angle of 90° is therefore balanced for primary forces, for primary and secondary and all higher orders of couples, but is unbalanced for secondary forces.

The unbalanced secondary force in the resultant of the unbalanced secondary force from each of the four-cylinder engines. This has just been shown to have the value \((5M_2 a^2/l)\cos 2\theta.

Combining these together it will be found that the magnitude of the resultant is very nearly \((7M_2 a^2/l)\cos 2\theta\), and that this alternating force acts horizontally.

The 6-cylinder engine of type A with equal reciprocating masses and cranks set, the inner pair parallel, the next pair parallel and at 120° with the inner pair, and the outer pair parallel and at 240° with the inner pair, and with the pairs symmetrically pitched along the crank shaft, is balanced for primary and secondary forces and higher orders of couples, excluding orders divisible by 3; and for primary and secondary and all higher orders of couples. Practically it is a perfectly balanced engine.

V engines made up of six-cylinder engines of this kind are therefore in almost perfect balance.
The radial engine, type C, an equiangular n cylinder radial engine with the connecting rods coupled to one crank pin and with reciprocating masses per cylinder equal to M pounds, is balanced for primary reciprocating forces by a balance weight as opposite the crank pin calculated from
\[ W = \frac{NM}{2} \text{ pounds at crank radius.} \]
This is valid for all values of n except 1 and 2.

If further M, at crank radius in the equivalent of the unbalanced moving parts due to the crank arm, crank pin, and the n equal moving parts of the connecting rods, the natural balance weight to be added at crank radius diametrically opposite the crank pin to balance the reciprocating parts and the moving parts is \( nM \) pounds.

It is shown below that when the number of cylinders exceeds three, the secondary forces along the respective lines of stroke mutually balance.

If there are three cylinders, mutually at 120°, there is an unbalanced secondary force equivalent to that caused by a mass weighing \( \frac{1}{2} M^2 \) pounds concentrated at the crank pin of a crank of radius \( r \) and revolving twice as fast as the main crank, but in the opposite direction.

These statements are proved as follows.

Let \( \beta \) be the angle between adjacent lines of stroke so that \( \beta = 2\pi/n \). Resolving the crank angle always in the positive direction from any one of the n lines of stroke in the engine, it will be seen from Fig. 22 that the crank angle reckoned from the 1st line of stroke is \( \theta + (k - 1)\beta \).

The force along the 1st line of stroke is therefore
\[ F = A \cos \{ \theta + (k - 1)\beta \} + B \cos 2 \{ \theta + (k - 1)\beta \} \]
\[ A = \frac{M \omega^2 r}{L} \text{ and } B = \frac{M \omega^2 r^2}{L}. \]

The simultaneous values of the forces along each line of stroke is found from this equation by substituting in succession \( k = 1, k = 2, \ldots, \text{ to } k = n \).

To find the resultant force on the frame, each of the forces is resolved into components along mutually perpendicular fixed axes and their resultant is determined. The statements made above are easily seen to follow.

These results only apply strictly when the connecting rods are coupled directly to the crank pin. If they are coupled through a floating big end, articulated as it is called, then the expression \( A \cos \theta + 3 \cos 2\theta \) no longer gives the accelerating forces in the line of stroke with accuracy.

Whatever be the mechanical arrangement, however, if the engine is balanced the mass centre of all the moving parts remains at rest during the motion. Particular arrangements can therefore be examined from this point of view.

In conclusion a point may be mentioned which is of importance in internal combustion engines. The driving torque on the crank shaft is necessarily accompanied by an equal and opposite reaction on the frame. If this driving torque varies periodically it tends to set the frame in torsional oscillation. This is minimised by increasing the number of cylinders and arranging the sequence of firing so that the torque curve shall be as uniform as possible. The eight-cylinder engine of type A gives a torque curve of least variation. The six-cylinder engine next. The four-cylinder has a large variation per revolution.

The addition of a flywheel, although controlling the variation of speed consequent upon torque variation, has no effect on the torsional reaction on the frame. That must follow every variation of the torque exerted by the crank shaft whether against a restistance or a resistance plus a flywheel. There is no difficulty in securing practical uniformity of torque in a steam engine.\(^4\) W. E. Dalby, Trans. Inst. Nav. Arch., 1909.

---

§ (2) CYCLES OF OPERATIONS.—When a definite quantity of any substance is subjected to a series of operations such that it returns finally to its initial condition in all respects, such a series is termed a "Cycle of Operations." Carnot's conception of a cycle of operations as a convenient means of considering quantitatively the changes undergone by the working substance of an ideal heat engine has proved invaluable in the development of the modern science of thermodynamics; its special merit is that as the working substance returns exactly to its initial state at the end of the cycle, so also does its internal energy, and hence we avoid the problem of discussing the measure of the change of energy of the working substance from its initial to its final state.

In considering the performance of internal combustion engines it is found convenient to divide cycles of operation into two classes, viz., (a) perfect cycles, and (b) imperfect cycles.

A cycle is said to be perfect when it is of maximum efficiency for the temperature range within which the engine works.

A perfect cycle is reversible, i.e., if the engine be worked backwards the heat transferred at each stage are exactly reversed.

A cycle is said to be imperfect when its efficiency is necessarily less than that of a perfect cycle for the same temperature range.

All the cycles of operation employed in actual internal combustion engines are imperfect in this sense; owing to the nature of the operations performed, their maximum efficiency is in every case necessarily less than the conceivable maximum for the range of temperature involved; the reasons for this are fully discussed later.

§ (3) Isothermal and Adiabatic Changes.—When the supply of heat to a substance is so regulated that its simultaneous changes of pressure and volume take place without change of temperature, the changes are termed isothermal.

When simultaneous changes of pressure and volume take place in a substance completely heat insulated from all external bodies, so that there can be neither loss nor gain of heat, the changes are said to be adiabatic. Expansion takes place, in general, against some external resistance (as, e.g., that offered by atmospheric pressure, or a loaded piston), and hence mechanical work must be done by the expanding substance in order to overcome this external resistance. Anticipating the first law of thermodynamics, it is evident that if heat be supplied to the expanding substance some, at least, of this will be expended in the external work of expansion. On the other hand, if no heat be supplied to the expanding substance, the heat-equivalent of the external work done must be supplied from the store of energy of the substance itself (termal internal energy), and its temperature will, in consequence, fall as the expansion proceeds. Clearly, then, on a pressure-volume diagram a curve indicating adiabatic changes from any initial condition is always steeper than a curve indicating isothermal changes from the same initial condition.

§ (4) The Two Laws of Thermodynamics.

(1) The First Law. The First Law states that heat is a form of energy; when heat is converted into mechanical energy, on the other hand, the quantity of mechanical work done is simply proportional to the quantity of heat converted.

The British Thermal Unit (B.T.U.) is the quantity of heat that will raise 1 lb. of water at 32°F., or near its temperature of maximum density, through 1° F. This quantity of heat if wholly converted into mechanical energy will perform 778 ft.-Ibs. of work. Thus, the "mechanical equivalent" of heat, is usually styled "duke's equivalent" and denoted by the symbol J. If the earth's average temperature be used, the value of the mechanical equivalent, then of the B.T.U., becomes approximately 1050. (See "Heat, Mechanical Equivalent of," § (5)).

(2) The Second Law. This puts us in mind one experience that heat, unlike, is unable to pass from one body to another at a higher temperature. Clausius' enunciation of this law is as follows: "It is impossible for a self-acting machine, unaided by any external agency, to convey heat from one body to another at a higher temperature." (See "Thermodynamics," § (1)).

§ (5) Carnot's Ideal Cycle.—This cycle, imagined by Carnot comprises two isothermal and two adiabatic processes (Fig. 1) during the first operation the working substance may be any whatever is caused to expand isothermally from 1 to 2 at a temperature T (Fig. 1), receiving during this operation a quantity of heat which may be denoted by N. At some point 2 the heat supply ceases and the expansion continues adiabatically until point 3 is reached. At point 3 the operation commences, viz., that of isothermal compression at some lower temperature t, in a point 4, such that if an adiabatic expansion adiabatically from 4, the point 1 is again reached; during
The isothermal compression $I$ is a quantity of heat, $h$, abstracted from the working substance. During the isothermal and adiabatic expansions $I$ and $I$, mechanical work is done by the substance, measured by the areas $122'1'1$ and $232'2'2$ respectively. During the isothermal and adiabatic compressions $34$ and $4I$, mechanical work is done on the substance, measured by the areas $34'3'3$, $41'4'4$ respectively. The complete cycle of operations leaves, therefore, a quantity of "useful work" done by the substance represented by the area $1234$ obtained by the expenditure of a quantity of heat $H$, of which a part, $h$, is rejected. By the First Law of Thermodynamics, therefore, the useful mechanical work $U$ (measured, for convenience, in heat-units) must be given by the relation

$$U = H - h.$$  \hspace{1cm} (1)

And the efficiency of the cycle, being the ratio of the useful work obtained to the energy expended, is

$$\text{Efficiency} = \frac{U}{H} = 1 - \frac{h}{H}. \hspace{1cm} (2)$$

This equation expresses the efficiency of the Carnot cycle in terms of the heat received at the upper limit of temperature $T$, and that rejected at the lower limit $t$.

Moreover, the cycle is reversible; if the engine be worked backwards and an amount of energy $U$ be given to the working substance, it will drive heat $h$ from the sink at temperature $t$ and give heat $H$ to the source at temperature $T$, passing through all the stages passed through during the direct process, and being in the same condition in all respects at each corresponding stage in the two.

§ 6. The Carnot Cycle a "Perfect" Cycle.---No conceivable engine, whatever its cycle, working between $T$ and $t$ can have a greater efficiency than the Carnot engine. For if it is possible, let there be such an engine $X$ using the same "source" of heat at temperature $T$, and the same "sink" of heat at temperature $t$.

Let $X$ be so coupled to the Carnot engine as to drive it backwards without doing external work; then during each revolution of the coupled engines the following exchanges take place:

- Engine $X$ takes heat $H'$ from the $T$-source, rejects heat $h'$ to the $t$-sink, and performs mechanical work $U' = H' - h'$; and

- The Carnot engine is reversible, and working backwards takes in heat $h'$ from the $t$-source, and rejects heat $H$ into the $T$-source in virtue of mechanical work $U$ done upon it, given by $U = H - h$. Thus, on the whole, no mechanical work is done, and $H - h = U' - h'$; hence $H - h = H - h - h'$. But since $X$ is the more efficient engine, it does the work $U$ for a less expenditure of heat from the source than that required by the Carnot engine. Thus $H'$ is less than $H$, and hence $h'$ is less than $h$. Thus the source at temperature $T$ gains heat $H - H'$, and the sink at a lower temperature $t$ loses an equal amount of heat $h - h'$. Hence by means of an infinite material agency—the two engines coupled—heat is transferred from a body at temperature $t$ to one at a higher temperature $T$, in violation of the Second Law of Thermodynamics. Thus engine $X$ cannot have a greater efficiency, working between $T$ and $t$, than that of the Carnot engine between the same temperatures.

Hence the Carnot cycle is of maximum efficiency, i.e., is a "Perfect" cycle.

It immediately follows that, within the same temperature range, all perfect cycles are of equal efficiency, the value of which in terms of heat received and heat rejected is as given in equation (2).

§ 7. Kelvin's Absolute Scale of Temperature.---Equation (2) expresses the efficiency in terms of heat quantities; it is next necessary to show how the efficiency may be expressed in terms of the limiting temperatures themselves.

Let $A_1B_1$ (Fig. 2) represent a portion of an isothermal, at temperature $T_1$, of the working substance, which may be any whatever. Along $A_1B_2$ let points $B_1$, $C_1$, $D_1$ be taken such that the expansions $A_1B_1$, $B_1C_1$, $C_1D_1$ correspond to the addition of equal quantities of heat, $H_1$, at the constant temperature $T_1$; and along $A_1$, $B_1$, $C_1$ draw a series of adiabatics of the substance.

Let $A_1B_2C_2$ be a second isothermal of the substance corresponding to some lower temperature $T_2$.

Then the quadrilaterals $A_2B_2$, $B_2C_2$, $C_2D_2$ are all equal; for each is the useful-work-area, $U$, of a Carnot engine diagram receiving heat $H_1$ at the higher temperature $T_1$, and rejecting heat at the lower temperature $T_2$. Moreover, since the efficiency is the same for each of these perfect cycles the amount of heat rejected at the lower temperature $T_2$ is the same for each. Let it be $H_2$. Hence, also $A_2B_2$, $B_2C_2$, $C_2D_2$
represent the isothermal changes at \( T_2 \) due to equal additions of heat, \( H_2 \), to the substance. Next suppose there to be drawn a series of isothermals \( A_1B_1C_1, A_2B_2C_2, \) such that the quadrilaterals \( A_1B_1A_2B_2, A_2B_2A_3B_3, \) are all equal; then it is evident that the two series of isothermal and adiabatic curves divide up the whole diagram into quadrilaterals of equal area. Now Kelvin defined equal temperature intervals as those between any two consecutive isothermals of this series; as this system of graduating temperatures is independent of the nature of the thermometric substance employed, it is styled the absolute scale of temperature. On this scale it is immediately obvious from the diagram that the efficiency of a Carnot engine working between \( T_1 \) and \( T_2 \) is twice as great as that between \( T_3 \) and \( T_4 \); and between \( T_5 \) and \( T_6 \), three times as great; and, generally, that the efficiency is proportional to the difference between the upper and lower temperature limits measured in this way, i.e.

\[
\frac{U}{H_2} = C(T_2 - T_1) \quad \ldots \ldots \ldots (3)
\]

where \( T_1 \) and \( T_2 \) are the upper and lower absolute temperature limits respectively.

The constant quantity \( C \) must be independent of \( T_1 \), but may be a function of \( T_2 \). It is termed Carnot's Function, and its value is immediately determined from the consideration that as equation (3) is to hold whatever \( T_2 \) may be, let \( T_2 \) be supposed so reduced (see Fig. 3) that the whole of the heat \( H_1 \) is converted into useful work \( U \). As \( U \) cannot conceivably be greater than this, it can only be inferred that when \( U = H_1 \), the temperature \( T_2 \) is the zero of the Kelvin scale; thus \( T_2 = 0 \) when \( U = H_1 \); hence equation (3) gives in this case \( 1 = C \) or

\[
C = \frac{1}{T_2} \quad \ldots \ldots \ldots (4)
\]

Thus Carnot's function is the reciprocal of the temperature reckoned from the Kelvin absolute zero.

The efficiency of the Carnot cycle can now be expressed in terms of the absolute temperatures of the limits; for if these be \( T_2 \) and \( T_3 \) respectively we have from equations (3) and (1)

\[
\text{Efficiency} = \frac{T_3 - T_2}{T_3} = 1 - \frac{T_2}{T_3} \quad \ldots \ldots \ldots (5)
\]

and this depends only on the ratio of the absolute temperatures between which the engine works. From equations (2) and (5) we have at once the important fundamental relation

\[
\frac{H_1}{T_2} = \frac{H_3}{T_3} \quad \ldots \ldots \ldots (6)
\]

i.e. Heat received = Abs. upper temp.,

Heat rejected = Abs. lower temp.

\[ 	ext{§ (8) Temperatures by Gas Thermometer.} \]

(T.2) Anticipating § (14) of Sec. 1, we know that for an ideal perfect gas \( p = \text{const.} \), where \( p \) is temperature as given by the gas-thermometer itself and \( R \) is constant, and it is easily shown,1 by a direct and independent investigation, that with such a gas as working substance, the efficiency of the Carnot cycle is expressed by \( 1 - \frac{T_3}{T_2} \), where \( T_3 \) and \( T_2 \) are the lower and upper gas-temperature limits respectively. Hence by equations (2) and (11) we have \( H_1/T_2 = T_3/T_2 \).

Kelvin abs. lower temp.,

Kelvin abs. upper temp.,

\[ \text{gas-thermometer lower temp.,} \]

\[ \text{gas-thermometer upper temp.} \]

In the gas-thermometer scale, the temperature interval between the freezing and boiling point of water is divided into 100 equal degrees, and this leads to the zero occurring at 273° below the freezing-point of water. If the same idea of degree be adopted for the Kelvin scale, then we shall have \( T_2 = T_1 \) and \( T_3 = T_2 \), and the readings, on other scales, will be identical. As the ordinary permanent gases approximate closely in their properties to those of a perfect gas, within the temperature range occurring in internal combustion engines, it is to be expected that the readings furnished by a gas-thermometer will correspond very closely with the temperatures of the Kelvin absolute scale. This is found to be the case, experiments by Joule and Kelvin on the flow of air and other permanent gases through porous plugs showing that for all practical purposes the readings of a gas-thermometer sensibly coincide with absolute temperatures on Kelvin's scale.2

Callendar (Phil. Mag., 1903) has given tables showing the correction to be made with air hydrogen, and other gas-thermometers in order to convert their readings to those of the Kelvin absolute scale. The correction is very small, amounting in the constant-volume hydrogen thermometer to not exceeding 1/100 of a degree between -10° C. and

1 See "Thermodynamics," § (20), 2 Ibid. § (12).
1000° C. With a constant-volume air thermometer the correction is slightly greater, but still very small. With gas-thermometers of the constant-pressure type the corrections are again slightly greater.

For all thermodynamic investigations on internal combustion engines, however, the readings of a gas-thermometer may be taken as absolute temperatures.

§ (9) Energy.—Let AB (Fig. 4) be any two points on the pressure-volume diagram of a substance, and suppose that by the addition of heat simultaneously values of its pressure and volume in passing from the state A to the state B are indicated by the full dark line joining A to B, and which may be of any form whatever.

Through A and B let there be drawn adiabatics; and through any point below A let there be drawn any isothermal, cutting these adiabatics in a and b respectively; and let \( t \) be the absolute temperature corresponding to the isothermal ab. Let the path from A to B be divided into a large number of small parts through each of which a small portion of an isothermal is drawn, as \( A_nB_n \); the corresponding temperature being \( T_n \), and through each extremity of each of these small isothermals let adiabatics be drawn cutting the isothermal ab. As at \( a_n, b_n \). The whole area \( A B a_b \) is thus divided up into a large number of elements, each of which is a Carnot engine diagram receiving heat \( h_n \) at temperature \( T_n \) during the isothermal expansion \( A_nB_n \), and rejecting heat \( h_n \) at temperature \( t \) during the isothermal compression \( b_n a_n \). The work-area \( A_nB_nb_na \) being denoted by \( U_n \), we have therefore, by equations (2) and (3),

\[
U_n = H_n \left( 1 - \frac{t}{T_n} \right),
\]

which may be written

\[
H_n - U_n = \frac{H_n}{T_n}, \quad \cdots \quad (7)
\]

Set out at length, therefore,

\[
\{H_1 + H_2 + H_3 + \ldots \} = \{U_1 + U_2 + U_3 + \ldots \}
\]

*But \( h = (H_n - U_n) \) by equation (1); setting this out at length also we have*

\[
\{H_1 + H_2 + H_3 + \ldots \} = \{U_1 + U_2 + U_3 + \ldots \},
\]

and accordingly,

\[
\{H_1 + H_2 + H_3 + \ldots \} = \{U_1 + U_2 + U_3 + \ldots \}.
\]

But \( h + h_2 + h_3 + \ldots = k \), the whole quantity of heat rejected by isothermal compression at \( t \), from \( b \) to \( a \); so that the result becomes

\[
\left( H_1 + H_2 + H_3 + \ldots \right) \frac{k}{T} = k \cdot \text{a constant,}
\]

whatever \( H_n \); \( H_1, H_2, H_3 \) may be.

When the number of parts into which the path AB is divided is indefinitely great, each of the quantities \( H_1, H_2, H_3 \) etc., is properly denoted by \( dH \), and we thus obtain the remarkable and important result

\[
\int_A^B \frac{dH}{T} = k, \quad \text{a constant.} \quad \cdots \quad (8)
\]

This is true whatever the form of the path between \( A \) and \( B \); it is true wherever \( A \) and \( B \) be taken on their respective adiabatics; and it is also true wherever the isothermal \( ab \) be drawn. The result may be expressed verbally as follows: For any working substance let any two adiabatics be drawn; take any point on one and any second point on the other; by means of a heat supply to the substance, varying in any manner whatever, let the condition of the substance be changed from the first point to that denoted by the second; divide each very small addition of heat, whatever its source, by the absolute temperature at which it is added. Then the algebraical sum of these quotients is constant in value.

Along any adiabatic \( dh = 0 \) by definition; thus in this case \( \int_A^B \frac{dH}{T} = 0. \)

Hence (Fig. 4), \( \int_A^B \frac{dH}{T} \) indicates a quantity which increases by a constant amount as we pass from one adiabatic \( AA \) to another \( BB \). Clausius gave the name Entropy to the value of the integral \( \int_A^B \frac{dH}{T} \) taken from some unknown zero of entropy up to the state \( A \). It is a function only of the state of the body. The zero of entropy in that of a body entirely deprived of heat, a condition unknown to us, but since we are concerned only with the changes of entropy this is immaterial, and equation (8) may be interpreted as expressing the fact that \( \int_A^B \frac{dH}{T} \), the difference of the entropies of the two conditions \( A \) and \( B \), is a constant. Entropy is usually denoted by
the symbol $\phi$; if, then, $\phi_1$ be that of A and $\phi_2$ that of B, we have, starting from any arbitrary zero,

$$\phi = \int_{\theta}^{\phi_1} \frac{dH}{T}; \quad \phi_2 = \int_{\phi_1}^{\phi} \frac{dH}{T},$$

and hence $\phi_1 - \phi = \int_{\phi_1}^{\phi_2} \frac{dH}{T}$. ... (9)

Practically entropy is reckoned from some assumed standard condition, as, e.g., at an absolute temperature $T$, to a substance, the corresponding change of entropy is $d\phi$; by equation (8) $d\phi = dH/T$. This may also be written $dH = T d\phi$, and $dH/d\phi = T$. Or, for a finite change,

$$\int dH = \int T d\phi.$$ ... (10)

The value of the entropy is usually determined in any specific case as is shown later in this article (vide § (29)). Fig. 5 shows a temperature-entropy diagram; it is usual to take the temperatures as ordinates and entropy as abscissae; let AB be a curve connecting temperature and entropy, and from any points $G (\phi_1, T)$ and $D (\phi_2, T)$ on this curve draw ordinates $CG$ and $DF$ respectively; then

$$\int_{\phi_1}^{\phi_2} dH = \int_{\phi_1}^{\phi_2} \phi d\phi = \text{area} MCDNM.$$

Hence the hatched area measures the heat supply to the substance from condition C to condition D. On the temperature-entropy, or "T-\phi" diagram any isothermal obviously appear as horizontal lines and all adiabatics (hatched) as vertical lines, as indicated in Fig. 6; thus the T-\phi diagram of any engine working on the Carnot cycle, whatever the working substance, is a rectangle as 1234. 12 representing the isothermal expansion at temperature $T$, 28 the adiabatic expansion from $T$ to $\phi$, 34 the isothermal compression at $\phi$, and 41 the adiabatic compression from $\phi$ to $T$ (compare Fig. 1). The area $\text{M12NM}$ represents $\eta_1$, the heat supplied during 12, while $\text{N34MN}$ represents $\delta_1$, the heat rejected during 34; hence the closed area 1234 represents $(\eta_1 - \delta_1)$, i.e., the heat converted into useful work. And it is immediately obvious from this diagram that the efficiency, $U/H$, being the ratio of the areas 1234 and M12NM, is also expressed by $(T-\phi)/T$.

And, generally, the "T-\phi" diagram of an engine working on any cycle is represented by an enclosed figure as, e.g., that shown hatched in Fig. 5, the area of which represents the useful work performed just as in the case of a pv diagram. Through the four extreme points of the boundary of this hatched area let horizontal and vertical lines be drawn as shown. Then the actual engine receives per cycle heat $H'$ represented by the area MA12BN, and rejects heat $H''$, represented by NCDAM, its efficiency being

$$\frac{H' - H''}{H'}$$, i.e., $1 - H''/H'$.

Now the temperatures between which this engine works are $T$ and $T'$; and 1234 is the T-\phi diagram of a Carnot engine working between the same temperatures, $H$ being now represented by M12NM, and $h$ by N34MN.

It is obvious that M12NM is greater than MA12BN and that N34MN is less than NCDAM, that is, that $H$ is greater than $H'$, and $h$ less than $h'$; thus $h/H$ is less than $h'/H'$, and, therefore, $(1 - h/H)$ is always greater than $(1 - h'/H')$; that is, the efficiency of the perfect cycle engine is a maximum, as has already been shown otherwise.

§ (10) ENTROPY IN A COMPLETE CYCLE.--Whatever the cycle of an engine, whether perfect or not, the working substance returns at the end of each cycle to its initial condition in all respects, and thus in a complete cycle there is no change of entropy; or, symbolically, for any complete cycle

$$\int_{\phi_1}^{\phi_2} \phi d\phi = 0.$$ ... (11)
In interpreting this equation all heat gained or lost by the substance as heat, whatever its source, is to be included. If, for example, the cycle includes processes, as of "unbalanced expansion," any heat generated within the substance itself during the substance of its turbulent motions must be included in the summation of equation (11). Any heat so generated is clearly a positive addition to the entropy summation.

If heat acquired by the substance in this, or other analogous manner, be not included in the summation, then it will be necessary to assert that only for any perfect cycle is equation (11) true, and that for an imperfect cycle $\frac{\Delta S}{\Delta T}$ is negative.

§ (11) Temperature-Entropy Diagrams.—These have proved of much value in studying the action of heat engines using water-steam as the working substance, but have not so far been much used in investigations connected with internal combustion engines.

Among further graphic aids to the study of heat engines may be mentioned the diagrams, introduced by Dr. Millor in 1904, of total-heat entropy ($H^\theta$), and total-heat pressure ($P^\theta$); both of these have already been found of service in steam-engine and steam-turbine problems, but they have not yet been employed in connection with internal combustion engines.

§ (12) Perfect Gases.—For the so-called "permanent" gases, of which (dry) air is the type, experiment has established the following results, termed the Gaussian Laws; they are conformable to by actual gases the more closely as they are raised in temperature the more highly above their condensation-point, that is, the more highly they are superheated. These Gaussian Laws are to be regarded, therefore, as the properties that would be exactly possessed by an absolutely ideal gas.

§ (13) Law 1 (Boyle's Law).—If temperature remains constant, then the product of pressure by volume is also constant. Hence the isotherms of a perfect gas on a pv diagram are rectangular hyperbolae with the coordinate axes as asymptotes.

§ (14) Law 2 (Charles's Law).—Under constant pressure all gases expand at one uniform rate with increase of temperature. As by Law 1, v=cT/p when T is constant, and by Law 2, v=cT when p is constant, it follows that $v=cT/p$ when both T and p change, i.e. $v=R(T/p)$, where R is some constant. This result, combining Laws 1 and 2 in one statement, is usually written

$$pv=RT,$$    \hspace{1cm}  (12)

and is termed the "Characteristic Equation" of a perfect gas.

If p and v suffer simultaneous increments $\Delta p$, $\Delta v$, $\Delta T$ respectively, then, as equation (12) always holds, we must have

$$p+\Delta p)(v+\Delta v)=R(T+\Delta T),$$

i.e.

$$p\Delta v+v\Delta p+\Delta p\Delta v=0,$$

and accordingly, in the limit, when the increments are indefinitely diminished,

$$pdv+vd\rho=RdT.$$    \hspace{1cm}  (12a)

is the invariable relation connecting $dv$, $dp$, and $dT$.

Here T is the strictly temperature measured on the absolute scale (§ (7)), but for all practical purposes the reading of a gas thermometer, or a good mercurial thermometer, is sufficiently accurate (vide § (8)). From equation (12) it appears that the expression $pdv$ measures the absolute temperature of a gas, and this property is much used in investigations of the action of internal combustion engines. The value of the constant R is determined in any specific case when the condition of the gas is known at any one instant. Thus for 1 lb. of air at 0° C. (T=273° C. abs.), when p is 14.7 lbs. per sq. in. (=2117 lbs. per sq. ft.), it is found that the volume v is 12.39 cub. ft.; hence from equation (12) $2117 \times 12.39=R \times 273$, whence $R=96$. Accordingly for air the characteristic equation is

$$pdv=96dT.$$    \hspace{1cm}  (12)

§ (15) Law 3 (Regnault's Law).—The specific heat at constant pressure is constant for any perfect gas. This quantity $(dH/\partial T)_p$ is commonly denoted by $k_p$.

Another important mode in which a gas may receive heat is at constant volume. The specific heat at constant volume $(dH/\partial T)_v$, is usually denoted by $k_v$. For air as the result of careful experiment the value of $k_v$ was determined by Regnault \(^1\) as 0.2376 C-Th. U. per lb.; from this the value of $k_p$ is obtained, by calculation, as 0.1680 C-Th. U. per lb.

§ (16) Law 4 (Joule's Law).—If a gas expands without doing any external work, its temperature remains unaltered. The volume of a gas is always maintained by some external pressure, and if a gas expands, mechanical work is necessarily done by it in overcoming this external pressure. If the gas be heat-insulated from all external sources, experience shows that its temperature rapidly falls during expansion; the external work is done at the expense of the internal energy of the gas. When there is no external work done there is no loss of internal energy, and, as Joule's Law shows, no loss of temperature; and this is true whatever the pressure of the gas.

Hence it is concluded that the internal energy of a gas is proportional to its absolute

\[^1\] These values are now considered to be too low; vide § (73); also in actual gases the values are not constant.
temperature. Thus in a perfect gas isothermal curves are also curves of equal internal energy, i.e. are "isentropics."

§(17) Symbolic Expression of the First Law of Thermodynamics. In general, when heat is supplied to a perfect gas, the pressure, volume, and temperature all undergo change, though at each instant the characteristic equation $pV = RT$ remains true. Suppose the addition of a small quantity of heat $dH$, to a gas at $p$, $V$, $T$, to cause these quantities to become $(p + \Delta p)$, $(v + \Delta v)$, $(T + \Delta T)$ respectively. The effect may be considered to be produced in two steps, viz. (1) a rise in temperature of $\Delta T$ (with corresponding rise in pressure $\Delta p$) at constant volume, and (2) an expansion at constant temperature between $T$ and $(T + \Delta T)$ through a volume $\Delta v$.

The heat necessary to produce the first step is $k_e \Delta T$, $k_e$ being by definition the quantity of heat necessary to raise the gas through $1^\circ C$ at constant volume. For the second step the expansion at constant temperature requires an amount of heat equivalent to the external work done, which lies between $\Delta p \Delta v$ and $(p + \Delta p) \Delta v$. And the sum of these two quantities is $dH$. Hence, in the limiting case we have

\[ dH = k_e \Delta T + \frac{\Delta p \Delta v}{J}. \tag{13} \]

i.e. Heat supplied = Increase of internal energy + External work done,

where $J$ is Joule's equivalent ($\frac{(14)}{4}$). This is the symbolic form of the First Law of Thermodynamics in the case of perfect gases.

§(18).—Several fundamentally important results are immediately deducible from this equation. Thus, in isothermal or "isentropic" expansion $T$ is constant; hence $k_e \Delta T = 0$; and accordingly in this case

\[ dH = \frac{\Delta p \Delta v}{J}. \tag{14} \]

so that the heat supplied is the exact equivalent of the external work done, the internal energy of the gas remaining unchanged. And, conversely, if a gas be isothermally compressed, the heat omitted is the exact equivalent of the work done upon the gas in compressing it. Integrating equation (14) we have, denoting by $H$, the heat supply necessary to change the volume from $V_0$ to $v$ isothermally:

\[ H = \int_{v_0}^{v} \frac{\Delta p \Delta v}{J} dv = \int_{v_0}^{v} \frac{dH}{J} = \int_{v_0}^{v} \left[ \frac{\frac{dv}{J}}{\frac{dH}{J}} \right] dv = \int_{v_0}^{v} \left[ \frac{dv}{J} \right] log \left( \frac{v}{v_0} \right). \tag{15} \]

The volume ratio of expansion $(v/v_0)$ is usually denoted by $r$; hence (15) is also written

Heat supplied $\equiv \int_{v_0}^{v} \frac{dH}{J} = \int_{v_0}^{v} \frac{dv}{J} log r$ \tag{15}

in thermal units, $T_o$ being the absolute isothermal-expansion-temperature.

§(19) Relation of $k_e$ to $k_v$.—With the same initial suppositions as in §(17), if the addition of $dH$ to the gas produces a rise of temperature $\Delta T$ (and corresponding volume increase $\Delta v$) at constant pressure $p$, then by the definition of $k_e$ we have at once $\Delta H = k_e \Delta T$; and, in the limit, $dH = k_e \Delta T$; and the final state of the gas being exactly the same in each case, we may write

\[ dH = k_e \Delta T = k_e \Delta T + \frac{\Delta p \Delta v}{J}. \]

But $pV = RT$, and as $p$ is here constant,

\[ p(dv/dT) = R, \text{ i.e. } \frac{dv}{dT} = \frac{R}{p}; \text{ hence } \]

\[ k_e \Delta T = k_v \Delta T + \frac{\Delta p \Delta v}{J}, \]

so that

\[ k_e - k_v = \frac{R}{p}. \tag{16} \]

that is, of course, the difference of the two specific heats is the thermal value of the external work done in raising 1 lb. of the gas through 1° C at constant pressure. The constant $R = p(dv/dT)$ is the measure of this external work in ft.-lbs.

(1) Value of $k_e$ for Air.—Regarded as a perfect gas, the constant value of $k_e$ for air can now be calculated; for we have seen (equation (12)) that $R = 0.070$, also $k_v = 0.2375$, and $J$ has been experimentally determined as 1000 ft.-lbs. per C.T.U.; hence

\[ k_e = \frac{0.070}{0.2375} = \frac{90}{1400}; \tag{16} \]

whence

\[ k_e = 0.0609 \text{ C.T.U. per lb.} \]

as already stated.

(2) Ratio of $k_e/k_v$; Value of $\gamma$.—The ratio of $k_e/k_v$, always denoted by $\gamma$, is of fundamental importance in all thermodynamic investigations; in the case of air, regarded as a perfect gas, we see that

\[ \gamma = \frac{k_e}{k_v} = 0.2375. \]

Assuming all heat-quantities to be expressed in energy in ft.-lbs.

Equation (13) becomes

\[ dH = k_e \Delta T + \frac{\Delta p \Delta v}{J}. \tag{13a} \]

while from equation (10)

\[ R = k_v \Delta v = k_v(\gamma - 1). \]

Hence by equation (12a)

\[ \frac{dH}{\gamma - 1} = k_v(\gamma - 1) \frac{dv}{\Delta T} = \frac{k_v}{J} \frac{dv}{\Delta T} + \frac{\Delta p \Delta v}{J} \]

so that

\[ k_e \Delta T = \frac{1}{\gamma - 1} \left( \frac{\Delta p \Delta v}{J} + \frac{\Delta p \Delta v}{J} \right) \]

and accordingly (13a) becomes

\[ dH = \frac{\Delta p \Delta v}{J} (\gamma - 1) \Delta T + \frac{\Delta p \Delta v}{J} \Delta T \]

which may also be written

\[ dH = \frac{1}{\gamma - 1} \left( \frac{\Delta p \Delta v}{J} + \frac{\Delta p \Delta v}{J} \right) \Delta T. \tag{13b} \]

\[ dH = \frac{1}{\gamma - 1} \left( \frac{\Delta p \Delta v}{J} + \frac{\Delta p \Delta v}{J} \right) \Delta T. \tag{13c} \]
This equation is sometimes useful in the analysis of actual indicator diagrams of internal combustion engines.1

The following formula giving $H - H_a$ readily in work-units, in terms of quantities easily measured from an ordinary indicator (psf) diagram, is also worthy of notice. We have

$$T = \frac{R}{\beta};$$

hence

$$\frac{dT}{T} = \frac{1}{R} d\beta;$$

and thus equation (13a) becomes

$$dH = \frac{\beta}{\gamma - 1} (\beta - \beta^*);$$

i.e.,

$$dH = \frac{1}{\gamma - 1} \frac{d\beta}{\beta - \beta^*}.$$

Integrating across from $H_a = H_b$ to $H_c$ gives

$$H - H_c = \frac{1}{\gamma - 1} (\beta - \beta^*) + \int_\beta^* \frac{d\beta}{\beta - \beta^*}.$$  

Thus $H - H_c$ is determined as $\beta, \beta^*$ are directly measurable, and $\int_\beta^* \frac{d\beta}{\beta - \beta^*}$ is readily found by planimeter measurement from the indicator diagram.

If the actual expansion (or compression) curve of a diagram can be replaced by an equation of the form $\beta^* = \text{constant}$ (vide § 22) of [fn], we have by differentiation

$$\frac{d\beta}{d\sigma} = \frac{\beta - \beta^*}{\beta - \beta^*};$$

i.e.,

$$d\beta = \frac{\beta - \beta^*}{\beta - \beta^*} d\sigma;$$

hence in this case equation (13a) takes the very simple form

$$dH = \frac{\beta - \beta^*}{\beta - \beta^*} d\sigma.$$  

If, during expansion, the gas loses heat, $dH + \sigma d\sigma$ is negative and hence $\beta$ must be greater than $\beta^*$. If, during compression, the gas loses heat, then $dH + \sigma d\sigma$ is also negative, a must be less than $\beta^*$.2

When $\beta^* = \text{constant}$, $\beta = \text{constant}$, and thus equation (13b) may be written

$$H - H_c = \frac{- \frac{\beta^* - \beta}{\beta - \beta^*}}{\frac{\beta - \beta^*}{\beta - \beta^*}} d\sigma,$$

or in integration and reduction this gives

$$H - H_c = \frac{1}{\gamma - 1} \ln \left( \frac{\beta}{\beta^*} \right).$$  

we see also equation (56) infra.

§ 20 THE ADIABATIC EQUATION OF A PERFECT GAS.—In adiabatic changes no heat enters or leaves the gas, and hence in equation (13) we symbolise this condition by putting $d\sigma = 0$. Thus in adiabatic change we have

$$k_\alpha dT + \frac{1}{\gamma - 1} d\beta = 0;$$  

which expresses that in this mode of expansion the external work is done wholly at the expense of the internal energy $U$ of the gas. As $p = RT/\beta$, and $R = \beta^2/\gamma - 1\gamma d\beta/(\gamma - 1)$, we may write (17)

$$k_\alpha dT + k_\alpha (\gamma - 1) \gamma d\beta = 0;$$

that is

$$\frac{d\beta}{\gamma - 1} \gamma d\beta = 0.$$  

Integrating, log $\beta = \gamma - 1$, log $\beta = \text{constant}$. If $\beta_0$ and $\beta_1$ be datum temperature and volume respectively,

$$\log \beta = \log \beta_0 + (\gamma - 1) \log \beta_1.$$  

Hence

$$\log \left( \frac{\beta}{\beta_0} \right) = \gamma - 1,$$

i.e.,

$$\log \left( \frac{\beta}{\beta_0} \right) = \gamma - 1,$$

and thus

$$\log \left( \frac{\beta}{\beta_0} \right) = \gamma - 1.$$  

This is the adiabatic equation of a perfect gas in terms of volume and temperature. An $p\beta = \text{RT}$ always, equation (10) may easily be expressed in one of the following three ways:

$$p = \rho \beta^\gamma \ldots \text{ a constant},$$  

$$\frac{\beta}{\beta_0} = \rho \beta^\gamma \ldots \text{ a constant},$$  

$$T = \gamma - 1.$$  

§ 21 EXPANSION TO INFINITY.—If unit mass of a perfect gas be expanded (1) isothermally and (2) adiabatically, from an initial condition $T_0, \nu_0, V_0$ to an infinite volume, the external work done being $\int_{V_0}^{V_\infty} \frac{p\beta}{\beta - \beta^*}$ is infinite in the isothermal case, by equation (16').

In the adiabatic case, however, we have

$$\text{Work to infinity} \Rightarrow \int_{V_0}^{V_\infty} \frac{p\beta}{\beta - \beta^*} \int_{V_0}^{V_\infty} \frac{d\beta}{\beta - \beta^*}$$

by equation (20); that is,

$$\text{Work to infinity} \Rightarrow \rho \beta_0 \gamma \int_{\gamma - 1}^{\gamma - 1} \frac{d\beta}{\beta - \beta^*}$$

(23)

As $p\beta_0 = \text{RT}_0 = k_\alpha (\gamma - 1)T_0$, this may also be written

$$\text{Work to infinity} = k_\alpha T_0.$$  

An obvious truth, as in this case the whole internal energy of the gas is converted into external work.

For 1 lb. of dry air at 0° C. and one atmosphere pressure, regarded as a perfect gas, the external work done in expanding to infinity would thus be 304.8 × 2536 × 14 lbs. 11.4 ft. lbs., or 8,980 ft. lbs. As $r_v = 12.3$ in. or ft., this may also be expressed by saying that 1 cft. at 0° C. and one atmosphere, expanding to infinity in the circum-

1 Whipple, The Internal Combustion Engine, pp. 61-96.

---

1 Whipple, The Internal Combustion Engine, pp. 61-96.
ENGINE, THERMODYNAMICS OF INTERNAL COMBUSTION

Atmosphere here supposed, would perform about \( 2 \) ft.-tons of work.

\( \rho \) \( \text{(20) Curves of Equation } \rho v^m = \text{constant.} \)

All the curves of this family have a general resemblance to the hyperbola for positive values of the constant index \( n \), the co-ordinate axes being asymptotes. Such curves are frequently of service in the study of heat-engine diagrams as it is often found possible to express actual compression or expansion curves by assigning a suitable value to \( n \). It is thus useful to establish some geometric and thermodynamic properties connected with them.

Thus (Fig. 8), let \( D_1 C_1, D_2 C_2 \) be two curves whose equations are \( \rho v^m = a_1, \rho v^m = a_2 \) respectively.

Property 1. — Let the curves be cut by any horizontal, i.e., constant pressure line \( NH_1 B_1 \). Denote \( NH_1 \) by \( v_1, NH_2 \) by \( v_2 \) and \( OB \) by \( p \).

Then

\[
\rho v_a = a_2
\]

and therefore

\[
\left( \frac{v_2}{v_1} \right)^n = \left( \frac{a_2}{a_1} \right)^n. \tag{25}
\]

Hence any horizontal (constant pressure) line cuts the two curves in such manner that the ratio \( NH_1/NH_2 \), i.e., \( \frac{v_2}{v_1} \), is constant.

Property 2. — Let the same two curves be cut by any vertical, i.e., constant volume, line \( MC \). Denote \( MC \) by \( p_1, MC_2 \) by \( p_2 \) and \( OM \) by \( v \).

Then

\[
\rho v^n = a_2
\]

and therefore \( \frac{p_2}{p_1} = \frac{a_2}{a_1} \), a constant. \( \tag{26} \)

Hence any vertical (constant volume) line cuts the two curves in such manner that the ratio \( MC_1/MC_2 \), i.e., \( \frac{p_2}{p_1} \), is constant.

Property 3. — Let the same two curves be cut by a third curve \( D_3 C_3 \) whose equation is \( \rho v^m = a_3 \). Denote \( Ob_1 \), by \( v_1, OB_1 \) by \( v_2 \) and \( OB_2 \) by \( p_2 \).

Then

\[
\rho v^m = a_3
\]

Hence

\[
\left( \frac{v_2}{v_1} \right)^n = \left( \frac{a_3}{a_1} \right)^n, \tag{27}
\]

and therefore

\[
\left( \frac{v_2}{v_1} \right) = \left( \frac{a_3}{a_1} \right)^{\frac{1}{n}}, \text{ a constant.} \tag{27}
\]

As this result is independent of \( a_3 \), we have the property that all the curves \( \rho v^m = \text{constant} \) cut the pair of \( \rho v^m \) curves in such manner that the value of the ratio \( \frac{v_2}{v_1} \), is constant.

Lastly, we have

\[
\frac{p_2^m}{p_1^m} = \frac{a_2}{a_1} = \left( \frac{p_2}{p_1} \right)^n, \tag{28}
\]

by equation (27); that is,

\[
\left( \frac{p_2}{p_1} \right) = \left( \frac{a_2}{a_1} \right)^{\frac{1}{n}} \text{ a constant}. \tag{29}
\]

This result being also independent of \( a_3 \), all the curves \( \rho v^m = \text{constant} \) cut the pair of \( \rho v^m \) curves in such manner that the value of the ratio \( \frac{p_2}{p_1} \), is constant.

\( \rho \) \( \text{(23) Application to the Carnot Diagram.} \)

The diagram of a Carnot cycle engine using a perfect gas as working substance (Fig. 9) consists of two isotherms \( p_1 = \text{constant} \), and two adiabats \( p_2 = \text{constant} \), compare Fig. 1.

Here \( m = 1, n = 1, \) and we have accordingly by equation (27)

\[
\left( \frac{v_2}{v_1} \right) = \left( \frac{p_2}{p_1} \right)^{\frac{1}{1}} = \left( \frac{p_2}{p_1} \right), \tag{30}
\]

or the ratios of isothermal expansion and compression are equal. And from (29) we have immediately also

\[
\left( \frac{p_2}{p_1} \right) = \left( \frac{a_2}{a_1} \right)^{\frac{1}{1}} = \left( \frac{a_2}{a_1} \right), \tag{31}
\]

or the ratios of adiabatic expansion and compression are also equal.

The total expansion ratio in \( (p_2/p_1) \) denote this by \( X \), and let \( r \) and \( p \) denote the isothermal and adiabatic expansion ratios respectively. Then as \( (v_2/v_1) = (p_2/p_1)(m/n) \), we have

\[
X = p. \tag{32}
\]

Now in this case

\[
u_1 = p_1 v_1^m, \quad v_2 = p_2 v_2^m,
\]

hence by equation (27)

\[
r = \left( \frac{p_2 v_2^m}{p_1 v_1^m} \right)^{\frac{1}{m-1}} = \left( \frac{p_2 v_2^m}{p_1 v_1^m} \right)^{\frac{1}{m-1}} \xrightarrow{\gamma=1} \left( \frac{v_2}{v_1} \right)^{\frac{1}{m-1}} \xrightarrow{\gamma=1} \left( \frac{v_2}{v_1} \right)^{\frac{1}{m-1}},
\]

i.e.,

\[
r = X \left( \frac{v_2}{v_1} \right)^{\frac{1}{m-1}}. \tag{33}
\]

Hence the isothermal expansion ratio depends upon both the total expansion ratio and the temperature limits. As \( r \) is necessarily
greater than 1, X must always be taken greater than \((\gamma - 1)/(\gamma - 1)\).

And as by equation (30) \(\rho = X/r\), we have by (31)
\[
\rho = (\gamma - 1)/\gamma - 1 . \quad (32)
\]

Thus the adiabatic expansion ratio depends only upon the temperature limits. By aid of equations (30), (31), and (32) the diagram can be completely drawn when \(T_1, T_2, T_3\), and one pressure, say \(p_p\), are given. Lastly, from equations (5) and (32) we have

\[
\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right) \gamma - 1 . \quad (32')
\]

And thus, in the Carnot cycle the efficiency depends only upon the ratio of (adiabatic) compression.

§(24) Further consequences of the Equation \(p^n = \text{constant}\).—The external work done when a gas expands from an initial volume \(v_0\) to any other volume \(V\) being \(\int_{v_0}^{v} p\,dv\), if the law connecting \(p\) and \(v\) be \(p^\rho = p_0v^\rho\), \(p^\rho = p_0v^\rho \times v^{\rho - n}\) and hence

\[
\text{Ext. work done} = p_0\rho v^\rho \int_{v_0}^{v} \frac{v^{-n + 1}}{v^{-n + 1}} \, dv ;
\]

that is
\[
\text{Ext. work} = p_0\rho v^\rho \left[ \frac{v^{-n + 1}}{-n + 1} \right]_{v_0}^{v} = p_0\rho v^\rho \left[ \frac{v^{-n + 1}}{-n + 1} \right]_{v_0}^{v}.
\]

which reduces immediately to the simple form,
\[
\text{Ext. work} = \frac{1}{1 - n} (p_v - p_0v_0) . \quad (33)
\]

As \(p^\rho = p_0v^\rho\) and \(p_0v_0 = 1T_0\), this equation may also be written
\[
\text{Ext. work} = \frac{1}{1 - n} [T_v - T_0] . \quad (34)
\]

This result shows that when a gas expands in accordance with the law \(p^\rho = \text{constant}\), the external work done is simply proportional to the change of temperature of the gas. As the initial temperature is \(T_0\), if \(n\) be greater than 1 the temperature falls during expansion, whereas if \(n\) be less than 1 the temperature rises as the expansion proceeds. When \(n = 1\) equation (34) assumes an indeterminate form, but this is already known to be the isothermal case, and the temperature remains constant during the expansion.

To determine the heat expanded we have by aid of equation (12)
\[
H = \int k_v(T - T_0) + \int \frac{p\,dv = k_v(T - T_0) + \frac{R}{1 - n} (T_v - T_0) ;}
\]

as \(R = k_v(\gamma - 1)\) this reduces to
\[
H = \gamma - 1 k_v(T - T_0) = \frac{k_v}{1 - n} (T_v - T_0), \quad (35)
\]

which shows that the heat expanded is also simply proportional to the change of temperature of the working gas, and that this expands with an apparent specific heat which is constant and equal to \(k_v(\gamma - 1)/\gamma - 1\). \(k_v\) is negative for values of \(n\) between 1 and \(\gamma\) and positive for all other values of \(n\).

\[\text{FIG. 10.}\]

A diagram showing the apparent specific heat when \(p^n = \text{constant}\.)

\[\text{FIG. 11.}\]

A diagram indicating any two conditions \((p_0, T_0, \phi_0)\) and \((p_v, T_v, \phi_v)\) respectively.
of unit mass of a perfect gas. It is required to express (\(\phi_2 - \phi_1\)) in terms of \(p_1, v_1, T_1, p_2, v_2,\) and \(T_2\).

Through \(A_1\) and \(A_2\) draw the isentropies (i.e., adiabatics) \(a_1a_2\) and \(a_2a_4\); then \((\phi_2 - \phi_1)\) is known if \(\mathcal{W}_1/\mathcal{T}_1\) can be calculated for any one path from any point on \(a_2a_4\) to any point on \(a_1a_2\). This can be immediately done if the path be of constant pressure, or constant volume, or constant temperature, and the results in each case will be identical; thus:

(i.) Constant Pressure Path. — Through \(A_1\) draw the constant pressure line \(A_1A'\), meeting the isentrope \(a_1a_2\) at \(A'\). Let \(\mathcal{W}_1(p_1, v_1, T_1)\) be any intermediate point; then \(p_1v_1^\gamma = T_1\), we have \(\mathcal{W}_1 = R\mathcal{T}_1\), and hence \(d\mathcal{W}_1 = R\mathcal{T}_1\,dT_1\); thus \(p_1dv = p_1\mathcal{T}_1\,dT_1 = R\mathcal{T}_1\).

Now by equations (9) and (13), expressing work-quantities in heat-units, we have

\[
\mathcal{W}_1 = \int_{T_1}^{T_2} k_v dT = k_v \int_{T_1}^{T_2} T^{1-\gamma} dt,
\]

or, as \(p_1dv = R\mathcal{T}_1\),

\[
\phi_2 - \phi_1 = k_v \left( \frac{T_2}{T_1} \right)^{1-\gamma} = k_v \left( \frac{p_2}{p_1} \right)^{1-\gamma},
\]

i.e.,

\[
\phi_2 - \phi_1 = k_v \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

But, by equation (21), as \(A'\) and \(A_2\) are both on the isentrope \(a_1a_2\),

\[
T' = T_2 \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

hence (37) becomes

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

which expresses the difference of entropy sought in terms of the pressure and temperature at \(A_1\) and \(A_2\).

As \(p_1v_1 = R\mathcal{T}_1, p_2v_2 = R\mathcal{T}_2\), we have

\[
\phi_2 - \phi_1 = \left( \frac{\mathcal{T}_2}{\mathcal{T}_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

hence (38) becomes

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

which expresses the difference of entropy in terms of the volume and temperature at \(A_1\) and \(A_2\).

This may be somewhat simplified; for \(k_v = k_v\); substituting therefore, equation (39) becomes

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

(40), which expresses the difference of entropy by adiabatic constant \(\gamma\), and

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

(41) becomes

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{p_2}{p_1} \right) \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

and

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{p_2}{p_1} \right) \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

278. ENGINES, THERMODYNAMICS OF INTERNAL COMBUSTION

As along an adiabatic \(p\) is constant, if the value of this constant be denoted by \(\beta\), equation (40) takes the simple form

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{p_2}{p_1} \right) \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

which is identical with equation (40).

(ii.) Constant Volume Path. — Referring again to Fig. I1, consider the change of entropy is proceeding along the constant volume path \(A_1A'\) between the two isentropes \(a_1a_2\) and \(A_2A'\).

In this case \(dv = 0\), and therefore \(p\,dv = 0\), no external work being done, hence we have

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

and thus

\[
\phi_2 - \phi_1 = k_v \log \left( \frac{T_2}{T_1} \right) \frac{p_2}{p_1} \left( \frac{T_2}{T_1} \right)^{1-\gamma},
\]

which is identical with equation (40).

(iii.) Constant Temperature Path. — Lastly, consider an isothermal path, as \(A_1A'\) (Fig. 11) between the two isentropes. Then from equations (16) and (17) we have at once

\[
\phi_2 - \phi_1 = \frac{d\mathcal{W}}{\mathcal{T}} = R\log \left( \frac{p_2}{p_1} \right),
\]

which is equation (40) again. Thus, proceeding from \(A_1\) to \(A_2\) by the iso-entropic paths of constant pressure, constant volume, or constant temperature, we are in each case led to the result that the difference of entropy of \(A_2\) and \(A_1\) is expressed by \(k_v \log \left( \frac{p_2}{p_1} \right)\), where \(\beta\) is the adiabatic constant \(\beta\).

§ 230. The Internal Combustion Engine: "Mixture." — All the preceding relations are strictly true only for an ideal perfect gas, which may be defined as a gas of which the
absolute temperature is simply proportional to the value of the product \( p v \). For all the ordinary "permanent" gases the difference between the actual volume, and the value of \( RT/p \) is so small that it is unnecessary to take it into account in investigations of the performance of internal combustion engines; in all such investigations it is therefore usual to assume that the effective temperature of the working mixture of gases is given by the value of the expression \( p v/RT \), with a suitable value assigned to the constant \( R \). Callendar has stated \(^1\) that the experimental evidence available indicates the error of this assumption to be certainly less than 1 per cent for a mixture at 2000° C., the composition of the mixture being known.

All internal combustion engines are essentially air engines wherein the air is very suddenly and very intensely heated by causing chemical action to take place throughout its volume; this is effected by "carburetting" the air, i.e. by mixing it with a relatively small quantity of some inflammable gas or vapour in order to produce an explosive mixture, and igniting this explosive mixture at a suitable instant.

Before explosion the mixture consists of air (usually somewhat moist), carburetted with town's gas, blast furnace gas, producer gas, "fuel oil" vapour, kerosene vapour, petrol vapour, benzol vapour, alcohol vapour, acetylene, etc., dependent upon the inflammable agent used, and diluted to a varying degree with some of the exhaust products from the preceding cycle; after complete combustion, and during the working stroke, the mixture consists of nitrogen, steam, carbonic acid gas, and usually some excess oxygen.

\(^{(27)}\) Cycles of Internal Combustion Engines.—The very numerous working cycles adopted, or suggested, in actual internal combustion engines are conveniently classified according to the condition in which the working substance receives its heat, thus we have:

- **Class I.** Cycles of combustion at constant volume.
- **Class II.** Cycles of combustion at constant pressure.
- **Class III.** Cycles of combustion at constant temperature.

\(^{(28)}\) Class I.—The Carnot cycle, already fully considered, typifies this class; all heat received is at constant temperature \( T \), and all heat rejected is at some constant lower temperature \( I \). The cycle is perfect, and therefore of maximum efficiency expressed by \((1 - T/2)\) (vide also equation \((32')\)).

An indicator diagram drawn to scale for an engine working on this cycle with air between 300° C. and 700° C. only is shown

| *Gaseous Explosions Committee, 1st Report, 1908.* |

In Fig. 12, although the maximum pressure attained in the case taken is about 225 lbs. per sq. in., the mean effective pressure is only about 11.5 lbs. per sq. in., or less than one forty-fifth of the maximum pressure. The engine would necessarily be designed to safely withstand the maximum pressure, and would thus be very heavy in relation to its power output. It has long been recognised, owing to this and other practical drawbacks, that the Carnot cycle is quite unsuitable as an actual working cycle, though within recent years its adoption was seriously proposed by Diesel \(^2\) but soon abandoned in favour of the new well-known constant pressure cycle finally adopted in this type of engine.

\(^{(29)}\) Class II. "Constant Pressure" Cycles.—In this class are included the American "Brayton" engine \((1873)\) with Simon's modified design, and also engines of the modern highly economical "Diesel" and "semi-Diesel" types.

The Brayton engine included a compressing pump and a working cylinder. The charge of carburetted air, taken in at atmospheric pressure, was first compressed by the pump and delivered into a receiver at a pressure of some 70 lbs. per sq. in. above atmosphere; from this receiver the working cylinder took its charge, the mixture being ignited on entering, inflammation of the contents of the receiver being provoked by the interpolation of a fine wire-gauze screen with somewhat in the manner of action of the Navy mine's safety lamp.

During the first portion of the working stroke the working cylinder thus received its mixture in an ignited condition at a pressure nearly equal to that in the receiver; at a suitable instant an inlet valve cut off communication with the receiver, the working stroke being then completed by the expansion of the flaring mixture contained in the cylinder. At the end of this stroke the exhaust valve was opened, and during the return stroke the burnt gas was expelled into the atmosphere, thus completing the cycle.
A working impulse occurred in every revolution, i.e. in every alternate stroke, so that the Brayton engine worked on what is now termed a "two-stroke" cycle; it will also be noted that in this engine the mode of ignition adopted increased not the pressure but the volume of the working mixture, the pressure in the working cylinder never quite equaling that in the receiver.

The cycle consisted of five operations, viz.: 

(a) Charging the pump with carburetted air.
(b) Compression of the charge into the receiver.
(c) Admitting the (ignited) compressed charge to the working cylinder.
(d) Expelling the burnt gas during the return (exhaust) stroke.

The ideal diagram of such a cycle is drawn by supposing no heating or throttling of the charge to occur during admission to the pump; no loss of the heat developed during compression into the receiver; no throttling of the charge on entering the working cylinder; no loss of heat by the flame to the working cylinder and piston; no back pressure during exhaust; and complete expulsion of all the burnt gas at the end of exhaust, which implies the assumption of no clearance in the working cylinder.

Although these conditions cannot be actually attained, they may be approximated to by skilled design.

The ideal diagram of the Brayton type of engine will therefore have the form shown in Fig. 13, and it is convenient to exhibit the diagrams of the pump and of the working cylinder superposed.

\[ P_{1} \] Diagram of Brayton Engine with Complete Expansion (Compare Fig. 23)

For 100 ft. of Air between Volume in Cu. Ft. 300° and 2000° C. (Abs.)

\[ V_{1} \]

AB represents the volume of the pump, AE that of the working cylinder; the carburetted charge is drawn in by the pump at atmospheric pressure AB, and compressed adiabatically along BC to the receiver pressure of about 70 lbs. per sq. in. above atmospheric, and then forced into the receiver at this pressure as indicated by the line CD.

From the receiver it enters the working cylinder at this pressure as indicated by CD, the supply being cut off at E; hence the expansion is adiabatic, and it is first supposed that this expansion is continued until the pressure has fallen to that of the atmosphere, at E. During the return stroke the burnt products are exhausted as indicated by the line EA, and the cycle is then complete.

The area ABEDA represents the work done by the compressing pump on the working mixture, while the area DFEAD represents the work done by the mixture upon the working piston. The difference, represented by the area BCPFE, accordingly represents the useful work done by the engine per cycle.

The notation adopted is shown in Fig. 13; the heat supplied is that corresponding to the line CD, during which the working mixture increases its volume at constant pressure, from \( v_{2} \) to \( v_{3} \), and is accordingly expressed by

\[ H = k_{6}(T_{2} - T_{3}) \] (43)

while the heat rejected is that during the constant pressure exhaust period EB (regarded as compression at constant pressure), from volume \( v_{3} \) to volume \( v_{4} \), and is accordingly given by

\[ h = k_{6}(T'_{3} - T_{4}) \] (44)

The efficiency, being the ratio of useful work done to heat supplied, is accordingly \( 1 - h/H \), i.e. \((1 - k_{6}H)\), which, by equations (43) and (44), becomes

\[ \text{Efficiency} = 1 - \frac{T'_{3} - T_{4}}{T_{2} - T_{3}} \] (45)

But the expansion and compression curves being adiabatic, we have by (22) (Property 1)

\[ T_{3} = T_{2} \]

\[ \frac{v_{3}}{v_{2}} = \frac{T_{3}}{T_{2}} \]

and as the working mixture obeys the law

\[ pv = RT \]

\[ \frac{v_{3}}{v_{4}} = \frac{T_{3}}{T_{4}} \]

and hence by (40)

\[ T_{4} = T'_{3} \]

\[ \frac{v_{3}}{v_{4}} = \frac{T_{3}}{T_{4}} \]

Accordingly

\[ T_{3} = T_{4} \]

\[ \frac{v_{3}}{v_{4}} = \frac{T_{3}}{T_{4}} \]

Thus, by equation (45) the efficiency may be simply expressed in the form

\[ \text{Efficiency} = 1 - \left( 1 - \frac{T_{3}}{T_{4}} \right) \] (47)

Hence when expansion is continued down to atmospheric (i.e. pump suction) pressure, the efficiency depends only upon the degree of compression BC.

The efficiency may also be expressed in
terms of the equal ratios of adiabatic volume change; if $\rho$ denotes the ratio of adiabatic expansion $v_t/v_w$ and $1/(\rho)$ denotes that of adiabatic compression $(v_w/v_t)$ by equation (48), then by equation (23) we have

$$\left(\frac{v_w}{v_t}\right) 1 - \left(\frac{1}{\rho}\right) \gamma - 1$$

whence, by (47),

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right) \gamma - 1,$$  

which expresses the efficiency in terms of the compression ratio alone, and has the same form as for a Carnot cycle. It will be observed that the cycle is imperfect, as the efficiency $1 - T_1/T_2$ in necessarily always less than $1 - T_1/T_2$. $\text{(39)}$ class 11. (continued).--Actually, it was found to be impracticable to continue the expansion so far that the pressure at release

![Diagram of Brayton Engine](image)

**Fig. 14.**

It had fallen to atmospheric, and accordingly the ideal practical indicator diagram would be as shown in Fig. 14. The efficiency is clearly less than in the case illustrated by Fig. 13, as, although the heat received remains unchanged, the useful work done per cycle is now reduced by an amount represented by the $\Delta t$ of the diagram [Fig. 14]. As before, the efficiency is expressed by $1 - k/H$, where $H = k_1 T_1 - T_2$. The total heat injected, $k_1$, is, however, now the sum of that rejected during the constant volume period 11, and that rejected during the constant pressure period 12; thus, since

$$k = k_1 T_1 - T_1 + k_2 (T_2 - T_3),$$

and accordingly (as $\gamma = k_2 \beta_2$), the efficiency is given by

$$\text{Efficiency} = 1 - T_1 \gamma - (T_2 - T_3) \gamma - T_3 - T_2.$$  

This expression does not admit of simplification in terms of the temperatures.

We may thermodynamically consider that all the action takes place in a closed working cylinder $v_w$ being the clearance volume initially filled with a charge of mixture at pressure $p_w$ and temperature $T_w$; the volume swept through by the working piston being $v_w - v_t$ per stroke.

Let the total expansion ratio $(v_t/p_w)$ be denoted by $N$, the expansion ratio of constant pressure $(v_t/p_w)$ by $\omega$, and the adiabatic compression ratio $(v_w/v_t)$ by $1/N$. Then by aid of equations (12) and (22) it is readily found that

$$T_2 = \omega_T - T_1 \gamma - (\gamma - 1)(N - 1) \gamma.$$  

$\text{(31)}$ The Diesel Engine. -- The other important cycle falling within Class II is that of the Diesel engine in its present form. As already stated, $\text{(28)}$, Diesel originally proposed to use the Carnot cycle, but in a paper read before the Paris Congress in 1900 he announced the cycle finally adopted after extended experiment as comprising the following five operations performed during four strokes of the working piston, the same vessel acting alternately as compressor and working cylinder (Fig. 15):

(1) (1st Stroke). -- Suction of air at atmospheric pressure $P_1$.

(2) (2nd Stroke). -- Adiabatic compression of the air, $P_2$.

(3) (3rd Stroke; First Portion). -- Regulated admission of the carburetted petrol (liquid or gaseous fuel) so as to maintain constant

![Ideal Diagram of Diesel Engine](image)

**Fig. 15.**

pressure during combustion for a portion of the working stroke $CP$.

(4) (3rd Stroke; Second Portion). -- Cut-off of fuel supply and adiabatic expansion of the heated mixture to the end of the working stroke $FL$.

(5) (4th Stroke). -- Opening of exhaust with immediate fall of pressure and temperature at constant volume $F_2$, and subsequent expansion of the burnt gases into the atmosphere during the exhaust stroke $KL$.

This completes the cycle; it will be observed that one working stroke only occurs in every four, and the cycle is accordingly of the "four-stroke" type.
From Fig. 13 it is clear that the areas representing work done on the piston are:

- During suction: +1EKNM
- During compression: -KGMN
- During working stroke: +MCFHNN
- During exhaust: -KLMN

Not useful work per cycle = -QFIHO

Thermodynamically we may obviously consider that the same mass of air is constantly enclosed within the working cylinder, this being heated at constant pressure during CE, and cooled at constant volume during HK. Thus, in the ideal case, the heat account is as follows:

\[ \text{Heat received} = H = k(T_2 - T_1) \]
\[ \text{Heat rejected} = k = k(T_2 - T_c) \]
\[ \text{Work done} = (H - k) = k(T_2 - T_1) - k(T_2 - T_c) \]

And therefore:

\[ \text{Efficiency} = 1 - \frac{k}{H} = 1 - \frac{k(T_2 - T_c)}{k(T_2 - T_1)} = 1 - \frac{T_c - T_1}{T_2 - T_1} \]  

(62)

This is immediately deducible from equation (60), which is reduced to the Diesel cycle by putting \( T_c = T_1 \).

Similarly, referring to equation (61), this reduces to the Diesel case by putting \( x = \rho \); and thus we have for the Diesel cycle:

\[ \text{Efficiency} = 1 - \left( \frac{1}{\rho} \right) \frac{\gamma - 1}{\gamma} \]  

(63)

where \( 1/\rho \) is the ratio of adiabatic compression \( (v_0/v_C) \), and \( \sigma \) is the ratio of expansion at constant pressure \( (v_0/v_C) \).

This case includes also that of the numerous so-called "semi-Diesel" engines, as, e.g., of the Peter, Blackburne, Ruston, etc., designs.

As the constant pressure expansion ratio, \( \sigma \), is reduced towards the value unity, the value of the efficiency given by equation (63) continually approaches towards the limiting value 1 - \((1/\rho)^{1/\gamma}\).

This conclusion of theory is apparently realised in practice. In Diesel engines the power is reduced by diminishing the extent of the constant pressure expansion, i.e. by reducing \( \sigma \); the following figures from tests made by Mr. Ado Clrik show the indicated thermal efficiencies obtained:

<table>
<thead>
<tr>

</tbody>
</table>

The Diesel cycle is clearly of the "imperfect" class.

§ (32) Class III. The "Constant Volume" Cycle. In this class is included by far the largest number of actual internal combustion engines, ranging from the early Le Monir and Hugon types to the modern Clark two-stroke and de Rochas, or Otto, four-stroke designs. A very large proportion of the external number of small internal combustion engines of the present day are worked on the Otto "four-stroke" cycle, while the Clark two-stroke cycle is extensively adopted in the larger types of stationary gas engines.

The Le Monir Engine. In the Le Monir gas engine (1869)—now completely obsoleteto account of its very low efficiency—the mode of working was evidently inspired by that of the ordinary steam engine. During the first portion of the stroke the working piston draws into the cylinder a charge of cold gas and air at atmospheric pressure; at an arranged point a slide valve cut off the supply, and simultaneously the charge within the cylinder was ignited, the temperature (and consequently the pressure) suddenly rising greatly; the working stroke was then completed by the expansion of this mass of heated high-pressure gas; during the return stroke the heated gas were exhausted into the atmosphere, thus completing the cycle.

Further following the steam engine, this cycle was caused to occur alternately on each side of the working piston, thus making the engine "double-acting"; thus a working impulse was obtained in every stroke. The

![Diagram of LeMonir Engine](image-url)

Lenoir engine worked very quietly and smoothly, but was abandoned on account of its very high consumption of gas in favour of more economical types.

The ideal diagram is shown in Fig. 10, wherein it is supposed that the cylinder has no clearance and that the expansion is carried so far that the pressure at the end of the stroke is that of the atmosphere. The volume swept through per stroke by the piston in AB during the portion AB the carburetted charge
is shown in Fig. 17; and it is clear that the heat received, H, is the same as in the preceding case, viz. $H_k(T_k - T_0)$; the heat rejected, $k$, is however, now the sum of that during the constant volume drop $H_k$, and the constant pressure shrinkage $H_k$ and thus

$$k = k(T_k - T_0) + k_{cP}(T).$$

Hence the efficiency, $1 - h/H$, is expressed by

$$\eta = \frac{H_k(T_k - T_0) + H_k}{H_k(T_k - T_0)} = \frac{H_k}{H_k} = 1,$$

or again, in terms of the ratio $(T_p/k)$ only,

$$\eta = 1 - \frac{1}{\gamma - 1} \frac{T_p}{T_0} = 1 - \frac{1}{\gamma - 1},$$

when $T_p = T_0$, $(T_p/k)$ decreases and equation (60) then reduces to equation (58). Also as $H_k/T_0$, $T_0$ decreases, equation (58) then reduces to equation (56). The efficiency is clearly less in this case than in the preceding one, since, with the same expenditure of heat, the useful work is less by the amount $H_k$, due to the incomplete expansion.

§ (33) Class III (continued). (i) The Free Piston Engine. — The Lenoir type of engine was superseded by a simpler design originally proposed by Harris and Maffeo (1857), but first rendered practicable by Otto and Langen in their "Free Piston Engine" of 1867. This essentially comprised a very long vertical cylinder fitted with a heavy free piston beneath which a charge of unburnt air was exploded, driving the piston upwards as a projectile driven from a gun; the heavy piston acquired considerable momentum, and continued its upward motion until the working mixture had expanded to about six times its original volume and to a pressure considerably below that of the atmospheric pressure by $H$. Then $T_1', T_0'$, $p_0'$, and by equation (22) $T_0' - T_1'(p_0'/p_0)^{1/(\gamma - 1)}$. Accordingly equation (60) may also be written

$$\eta = 1 - \frac{1}{\gamma - 1} \frac{T_p}{T_0},$$

$$\eta = 1 - \frac{1}{\gamma - 1} \frac{T_p}{T_0},$$

when $T_p = T_0$, $(T_p/k)$ decreases and equation (60) then reduces to equation (58). Also as $H_k/T_0$, $T_0$ decreases, equation (58) then reduces to equation (56). The efficiency is clearly less in this case than in the preceding one, since, with the same expenditure of heat, the useful work is less by the amount $H_k$, due to the incomplete expansion.
atmosphere. During its descent by gravity, and excess atmosphere pressure upon its upper surface, it engaged with, and drove, the crank-shaft through a ratchet and pawl device. The engine was excessively noisy and mechanically unsatisfactory, but the rapid and extended expansion, and subsequent slower cooling, of the working mixture resulted in a considerably increased efficiency compared with earlier types.

An ideal diagram is shown in Fig. 18: the charge of carburetted air at atmospheric pressure \( p_0 \) and temperature \( T_0 \) is drawn into the cylinder as indicated by \( AB \), and exploded at constant volume \( v_0 \) (=\( AB \)), its pressure rising to \( p_1 \) and temperature to \( T \) as indicated by \( BP \); the piston immediately rises rapidly, the charge expanding adiabatically to \( K \) when the piston momentarily stops. The downward (working) stroke now follows under the combined action of gravity and excess atmosphere pressure, the mixture being compressed isothermally from \( K \) to \( B \)—the in the absence of the working stroke, and finally expelled at constant pressure as indicated by \( HA \).

As before, in the working stroke only is considered by the area \( HBEH \); clearly also the heat supplied, \( H_1 \), is expressed by \( H_1 = k_1(T_0 - T_0) \), while the heat rejected, \( K_1 \), is given by \( K_1 = R_1 \log_{e} r \), where \( r \) is the ratio of isothermal compression \( (v/v_0) \); vide § (18).

Hence the efficiency \( = 1 - \frac{h_1}{H_1} = 1 - \frac{R_1 \log_{e} r}{k_1(T_0 - T_0)} \).

i.e. \( R = k_2 - k_1 \).

Efficiency \( = 1 - \frac{\gamma - 1}{(\gamma - 1) \log_{e} r} \) \( (T_0 v_0) \) \( - 1 \) \( (T_0 v_0) \).

(ii) The Beun de Rochas, or Otto, and the Clerk Cycles.—Finally there remain to be considered engines working upon the Beun de Rochas, or Otto, "four-stroke," and the Clerk "two-stroke," cycles, which may be considered to include between them all internal combustion engines of the present day. In all these engines combustion is caused to occur at constant volume with previous compression of the working charge.

§ (34) The Clerk Cycle.—The first case to be taken is that in which—as in the Clerk cycle—the engine comprises a compression pump and separate working cylinder, the compressing pump taking in a carburetted charge at atmospheric pressure and temperature and compressing this either directly into the combustion chamber of the working cylinder, or into an intermediate receiver from which the working cylinder in turn takes its compressed charge, which is then ignited (exploded) at constant volume, and performs the working stroke by its subsequent expansion.

Six separate operations may be here distinguished, viz.:

1. **Pump suction**—Charging the pump with carburetted air.
2. **Pump compression**—Compressing the charge into the receiver, or combustion chamber of working cylinder.
3. **Supply of compressed charge from receiver to working cylinder, when receiver is included.**
4. **Explosion of charge at constant volume in working cylinder.**
5. **Expansion of exploded charge during working stroke.**
6. **Expulsion of exhaust gases at the end of the working stroke.**

In considering an ideal diagram for this case the following assumptions are made:

1. That the charge is compressed adiabatically.
2. That none of the heat of compression is lost in the receiver.
3. That the charge is neither heated nor cooled on entering the combustion chamber of the working cylinder.
4. That the explosion occurs instantaneously, and with almost no loss of heat to the walls of the combustion chamber.
5. That the expansion during the working stroke is adiabatic, i.e., that no heat exchange takes place with the cylinder walls, or piston crown, during expansion.
6. That there are no losses by throttling or back pressure.

An ideal diagram embodying these assumptions is shown in Fig. 19, wherein it is also supposed that the expansion is continued so far that the pressure has fallen to \( p_0 \)—that of
the atmosphere—a condition not practically attainable, and also that the working cylinder has no clearance; thus the pump volume is AB, and the working cylinder volume AE.

During the pump suction stroke a volume of carburetted air is taken in at atmospheric pressure and temperature represented by AB, doing work + OABK upon the pump piston.

This is next compressed adiabatically along BO and delivered into the receiver at the constant pressure p0 along CQ; thus the pump diagram is − OKBCQO.

The charge next enters the cylinder along CQ, doing work + OQCM upon the working piston, and is then expanded at constant volume p0, the pressure instantly rising as indicated by CE, with subsequent adiabatic expansion DE to atmospheric pressure at E, doing work upon the piston represented by + EFENM. At E the exhaust opens and the burnt gases are expelled at atmospheric pressure p0, doing work represented by − EAON; this completes the cycle.

The work done is therefore

\[ \text{work} = \text{OABK} − \text{OKBCQO} + \text{OQCM} + \text{EFENM} − \text{EAON} = \text{BCFEB}, \]

and thus the useful work done per cycle is represented by the enclosed area BCFEB.

Thermodynamically the whole action may be conceived as taking place in a closed cylinder of clearance volume Al, IE being the volume swept through by the piston. Commencing at the point C, heat H is added to the charge to an amount given by the equation \( \Pi = k_{c}(\Pi - l) \); during expansion there is no communication of heat; during exhaust from E to B heat, \( h \), is rejected, given by \( h = k_{e}(\Pi - l) \); while during compression BC there is no communication of heat.

Hence the efficiency, 1 − H/\Pi, is expressed by

\[ \text{efficiency} = 1 - \frac{k_{e}(\Pi - l)}{k_{c}(\Pi - l)} = 1 - \frac{\Pi - l_{c}}{\Pi - l_{e}}. \]  

(93)

The efficiency may also be expressed in terms of \( T_2, l_0 \), and the ratio of adiabatic compression \( 1/f_p = (l_0/p_0) \). For, by equation (22),

\[ l_0 = \rho T_2^{\gamma - 1} \rho_0; \]

and

\[ T_2 = \left( \frac{\rho_0}{\rho} \right)^{\gamma - 1} T. \]

But also

\[ \rho_0 = \left( \frac{\rho_0}{\rho} \right) \left( \frac{T_2}{T} \right) \]

whence

\[ T_2 = \left( \frac{\rho}{\rho_0} \right)^{\gamma - 1} \left( \frac{T}{T_2} \right)^{\gamma - 1}. \]

Thus (90) may be written

\[ \text{efficienty} = 1 - \gamma \left( \frac{\rho_0}{\rho} \right)^{\gamma - 1} \left( \frac{T}{T_2} \right)^{\gamma - 1}. \]  

(64)

As \( \rho = (l_0/p_0)\gamma^{-1} \) and \( T = (l_0/p_0)\gamma^{-1}p_0^{\gamma/\gamma} \), it follows that

\[ T_2 = \left( \frac{\rho_0}{\rho} \right)^{\gamma - 1} \left( \frac{T}{l_0} \right)^{\gamma - 1}. \]

whence

\[ T_2 = \left( \frac{T}{l_0} \right)^{\gamma - 1}. \]

Hence, as

\[ l_0 = \rho T_2^{\gamma - 1}, \]

we have, on substituting in equation (90) and rededucing, the expression for the efficiency in terms of the total expansion and adiabatic compression ratio, \( c \),

\[ \text{efficiency} = 1 - \frac{\gamma}{\gamma - 1} \cdot \gamma - 1 \left( \frac{T}{l_0} \right)^{\gamma - 1}. \]  

(66)

As \( \gamma \) approaches \( X \) in value this expression continually approaches to \( 1 - (1/\gamma^{-1}) \) as a limiting value.

§ (35) The Clark Cycle with Incomplete Expansion.—Actually it has not been found practicable to continue the expansion so far that the pressure falls to that of the atmosphere; the next case for consideration, therefore, is that in which the pressure at the end of expansion exceeds that of the atmosphere.

An ideal diagram is shown in Fig. 29; as before, the heat supplied is \( H = k_{c}(\Pi - l) \), while the heat rejected is now given by

\[ h = k_{e}(\Pi - l) + k_{e}(\Pi - l_0); \]

Hence the efficiency, 1 − H/\Pi, is given by

\[ \text{efficiency} = 1 - \left( \frac{\Pi - l}{\Pi - l_0} \right)^{\gamma - 1} \left( \frac{T}{T_2} \right)^{\gamma - 1}. \]  

(77)

As \( T_2 = T_1(1/X)^{\gamma - 1}, l_0 = l_0 \gamma^{-1}, \) and \( T_2' = (X/l_0)^{\gamma} \),
ENGINES, THERMODYNAMICS OF INTERNAL COMBUSTION

we have on substitution and rearrangement from equation (67)

\[ \text{Efficiency} = 1 - \frac{(T_0(\gamma - 1)(\gamma - 1)(X_0) - \gamma)}{(T_0) - P_0} \]

when \( T_0 = T' \) (\( T'/\lambda = X'/\lambda \)) and (68) then reduces to the previous case, viz. equation (66).

\[ \text{Fig. 20.} \]

§ (30) THE BEAU DE ROCHEIS, OR OTTO, CYCLE.—The last and most important of all cycles of internal combustion engines is the "constant volume" cycle first proposed by Beau de Roches in 1863, and practically realised by Dr. Otto in his famous "Otto Silence" "gas engine" of 1876.

In this cycle there is no separate compressing pump, its function being discharged by the working cylinder itself. The sequence of operations is as follows, "stroke" referring to that of the working piston:

1. Stroking of the charge into the combustion chamber of the cylinder during the whole of the first out-stroke.
2. Compression of the charge into the combustion chamber of the cylinder during the whole of the first in-stroke.
3. Expansion of charge at end of first in-stroke.
4. Expansion of heated charge during the whole of the second out-stroke; this is the "working stroke."
5. Exhaust of the burnt gases into the atmosphere during the whole of the second in-stroke.

Thus the cycle requires for its performance four consecutive strokes of the working piston, whereas the term "four-stroke" cycle; and only one working impulse is obtained for each two revolutions of the crank-shaft.

An ideal diagram is shown in Fig. 21. During the first out-stroke the piston draws in the charge at atmospheric pressure, along LK, work being done on the piston represented by the area +MLKN. During the return stroke the volume AK is adiabatically compressed along KG to QC, the work done being represented by -NKLM.

Explosion is caused to occur at C, and the pressure instantly rises, at constant volume, as indicated by CG; during the second out-stroke the heated gases expand adiabatically along FH, doing work on the piston represented by +MP1NM, and at H the exhaust is opened to the atmosphere causing instant drop of pressure at constant volume HK. During the second in-stroke the burnt gases are expelled along KL into the atmosphere, work being done represented by -NKL; this completes the cycle. The work account is therefore

\[ +MLKN - NKLM + MP1NM \]

\[ -NKL = +PHIKC; \]

thus CPHIKC represents the useful work done per cycle.

Thermodynamically the action may be conceived as taking place in the same lines of air always enclosed in the working cylinder, and subjected to the operations indicated by KC, CP, PH, and HK; thus the heat received is \( h = \frac{T_h}{T_p} \); while the heat rejected is \( k = \frac{T_h}{T_p} \). Hence the efficiency, \( 1 - h/H \), is given by the equation

\[ \text{Efficiency} = 1 - \frac{T_0}{T_0} \]

\[ - T_0 \]

This may be simplified and expressed in two other important ways. For by equation (12) and § (23)

\[ \text{Efficiency} = 1 - \frac{T_0}{T_0} \]

\[ - T_0 \]

\[ \text{Fig. 21.} \]

Prop. 2. We have \( T_0 \), only upon the ratio of the absolute temperatures at the beginning and end of combustion, and is independent of the explosion temperature. Obviously (70) may also be written

\[ \text{Efficiency} = 1 - \frac{T_0}{T_0} \]

which expresses it in terms of the ratio of absolute temperatures at the beginning and end of expansion; it is obvious that the cycle is imperfect. The second important simplification of (90) is the expression for the efficiency in terms of the
(adiabatic) ratio of compression \( (1/p) \). We have by equation (29)
\[
\left( \frac{T_2}{T_1} \right) = \left( \frac{V_2}{V_1} \right)^{-1} = \left( \frac{1}{p} \right)^{-1} = \left( \frac{1}{\gamma} \right)^{-1}.
\]
hence by (70)
\[
\text{Efficiency} = 1 - \left( \frac{1}{\gamma} \right)^{-1}, \quad \ldots \quad (71)
\]
showing that in the ideal Otto cycle the efficiency depends upon the compression ratio alone.

§ (37) Efficiency Formula.—On comparing equations (39), (48), and (71) the interesting fact emerges (first pointed out by Callendar) that in the three typical ideal cycles of constant temperature, constant pressure, and constant volume, the efficiency is expressed by the same formula, viz.
\[
\text{Efficiency} = 1 - \left( \frac{1}{\gamma} \right)^{-1}, \quad \ldots \quad (71)
\]
where \( (1/p) \) is the ratio of isentropic compression, and is thus the same, for the same value of \( p \) in all three cases.

It must be remembered, however, that in the constant temperature (Carnot) cycle the adiabatic compression raises the temperature of the working substance through the whole range from the lowest to the highest between which the engine works, whereas in this case the value of the efficiency is an absolute maximum, as has been shown. In the other two cases the adiabatic compression does not raise the substance from the lowest to the highest temperature, and the expression for the efficiency has a value necessarily less than in the Carnot case, though a maximum in each case for the particular cycle considered; these are, therefore, "imperfect" cycles in the sense as explained in § (2) supra.

In the constant temperature cycle all heat is received and rejected at constant temperature; in the cycles of constant pressure and constant volume heat is received at rising, and rejected at falling, temperature; also in the Carnot and Brayton cycles the expansion is "complete," which is not the case in the Otto cycle. Examination of equations (61), (62), and (66) shows the manner in which the value of the efficiency is further diminished by changes in the cycles imposed by practical considerations.

§ (38) Temperature-Entropy Diagrams of Typical Cycles.—In Figs. 22-29 are shown 'T'-'\phi' diagrams for the typical cycles of Classes I, II, and III, together with actual numerical values of maximum efficiency for uniform upper and lower absolute temperature limits assumed at 2000° C. and 300° C. respectively. Fig. 22 shows the 'T'-'\phi' diagram for the constant temperature Carnot cycle; as already pointed out (vide Fig. 5 and text) this takes the form of a rectangle, and the efficiency—which is independent of the breadth of the rectangle—is here an absolute maximum in value of \( 1 - 300/2000 = 0.85 \).

§ (39) The Brayton Engine.—Fig. 23 shows the 'T'-'\phi' diagram of the constant pressure cycle of the Brayton engine, with complete expansion, as described in § (29) and Fig. 13. The entropy along the adiabatic compression is taken as an arbitrary zero; thus on any vertical, as MI in Fig. 23, take the point B at the 300° C. level. Then, by aid of equation (21), \( T = (p_2/p_1)^{\gamma-1} \), and taking \( p_2 = 70 \) lbs. per sq. in. and \( p_1 = 14.7 \) lbs. per sq. in., determines \( T = 488^\circ \) C.; this gives the point C on MI and thus determines BC, the isentropic corresponding to the adiabatic compression of Fig. 13. Through C draw the curve whose equation is \( \phi = b \), i.e., \( \phi = T \) (see equation (39)), and let this cut a horizontal through 2000° C. in F; then GF on Fig. 23 represents the constant pressure expansion line of Fig. 13. Through F draw a vertical meeting the curve \( \phi = b \), i.e., \( \phi = T \) in E; then FE is the isentropic corresponding to the adiabatic expansion line in Fig. 13, while the curve BE represents the constant pressure compression of Fig. 13.

Agreeably with equation (10) (see also Fig. 5) the efficiency in this case is expressed by the ratio \( \text{Area BCEF}/\text{Area MCFN} \), which, by direct
plummet measurement—as may be verified by calculation from equation (45)—has here the value 0.30.

The corresponding Carnot engine would take in heats HMF, and reject heat NFBM, with corresponding efficiency of 0.85. The Brayton engine takes in the smaller quantity of heat MCFN and rejects the larger quantity NEFBM, with resultant reduction in the value of its efficiency to 0.36.

§ (40) The Brayton engine with incomplete expansion.—Fig. 24 shows the T-φ diagram of the Brayton engine with incomplete expansion, as shown in the ps diagram. Fig. 14. The temperature T₂ at release II is taken as 1450°C, and the drop of pressure HK at constant volume in Fig. 14 is represented on the T-φ diagram by the curved line HK calculated from the equation \( \phi = k_p \log \left(\frac{T_2}{P_2}\right) \).

Fig. 24 differs from Fig. 23 only in the useful heat area being reduced by the amount HK, which thus represents, in this case, the loss caused by incomplete expansion, and reduces the efficiency from 0.36 to 0.33.

§ (41) The Diesel engine.—The T-φ diagram of the Diesel engine is given in Fig. 25. Initially (see Fig. 15) \( T = 300°C \), \( P_0 = \) atmospheric pressure (14.7 lbs.), while \( P_e \) is assumed at the value usually in practice, viz. 500 lbs. per sq. in., and \( T' = 2000°C \).

Then by equation (21)

\[ T_p = (P_0/P_e) - 1/\gamma \times T' = 1830°C \; ; \]

thus the points K and C may be determined, and HK on Fig. 25 is then the isentropic corresponding to the adiabatic compression of Fig. 15.

Through C the curve \( \phi = k_p \log \left(\frac{P_2}{P_1}\right) \) is next drawn, cutting a horizontal through 2000°C at F, while through K the curve \( \phi = k_p \log \left(\frac{P_2}{P_1}\right) \) is drawn cutting a vertical through F in H. Then HK is the isentropic corresponding to the adiabatic expansion, and HK corresponds to the constant volume pressure drop at release of Fig. 15.

For the efficiency in this case, either by calculation from equation (52) by direct measurement from the diagram of the ratio, we have for the area KCHHK/Area MCFN the value 0.46.

§ (42) The Linde engine.—In Fig. 26 is shown the T-φ diagram of the now entirely obsolete Class III Linde engine, with complete expansion, whose ps diagram is shown in Fig. 16. The diagram is constructed by taking the point B at 300°C on any vertical and drawing through this point the curve \( \phi = k_p \log \left(\frac{P_2}{P_1}\right) \) cutting a horizontal through 2000°C in F; thus BF represents the

\[
\text{Efficiency} = \frac{\text{Area BFE}}{\text{Area MBFKN}} = 0.20 \; ,
\]

as may also be determined by equation (51). The dotted line HK on Fig. 26 is the modification in the T-φ diagram due to incomplete expansion (compare Fig. 17), the
temperature at release H is assumed at 1400° C, and the curve HK is plotted from the equation \( \phi = k \log (1400/t) \) where \( \phi \) is in the form of entropy below that of H, viz. 0.321. The efficiency, being the value of the ratio Area BFEHK/Area MBFM, is now reduced to 0.25.

§ (43) FREE PISTON ENGINE.—The ideal T-\( \phi \) diagram of the Otto and Langen free piston engine is shown in Fig. 27, with which Fig. 18 may be compared. The initial point is B at 300° C, and the expansion raises the temperature, at constant volume, to 2000° C; this is represented on the diagram by the curve BF, plotted from the equation \( \phi = k \log (t) \), cutting a horizontal through 2000° C in F. The vertical EB is the isentropic corresponding to the subsequent adiabatic expansion during the rise of the heavy free piston, while the horizontal line ED represents the isothermal compression of the gases during the working down-stroke. The efficiency, either by direct measurement from the diagram of the value of the ratio Area BFEHK/Area MBFM, or by calculation from equation (42), has here the relatively high value 0.46; comparison with the previous diagram (Fig. 20) clearly shows the manner in which the efficiency is increased in value as a result of the compression being isothermal instead of at constant pressure.

§ (44) CLARK ENGINE.—The T-\( \phi \) diagram for the Clark constant-volume cycle, both with complete and incomplete expansion, is shown in Fig. 28; compare Figs. 10 and 20. The initial point B is at 300° C and the compression temperature \( t \) is assumed at 500° C; thus BC is the isentropic of adiabatic compression. The curve CP representing rise of temperature at constant volume (i.e., explosion) is next plotted from the adiabatic equation \( \phi = k \log (t/500) \), and by its intersection with a horizontal through 2000° C determines F; a vertical through F then meets the curve \( \phi = k \log (t/500) \) at E, and EF is then the isentropic of adiabatic expansion, while EB represents the operation of compression at constant pressure.

When the expansion is incomplete, assuming that at release the temperature is 1000° C, the curve HK, plotted from the equation

\[
T = \frac{2000}{t} \times \log \left( \frac{3000}{t} \right)
\]

Efficiency \( \phi = k \log (t) \)

with complete \( \phi = k \log (t) \)

and with incomplete \( \phi = k \log (t) \)

is given in Fig. 29. As before, the initial point K is taken on any vertical, at 300° C; the temperature of compression \( t \) is assumed at 600° C; hence the vertical line KT is the isentropic of adiabatic compression.

From C the curve \( \phi = k \log (t/500) \) is next plotted, cutting a horizontal through 2000° C.
in F; then the curve CF represents the increase of entropy during the explosion. Through F a vertical is drawn intersecting the curve \( \phi = k \log \left( \frac{T}{2000} \right) \) in H; then FH is the isentropic of adiabatic expansion, and the curve HK corresponds to the drop of pressure at constant volume which occurs at release.

The efficiency, either by direct measurement of the ratio Area KOFHK/Area MCFENL, or by calculation from equation (70) has here the value 0.56.

§ (40) IDEAL EFFICIENCIES.—Hence for a temperature range from 2000° C. (abs.) to 300° C., and with the other data assumed in the foregoing paragraphs, the maxima ideal efficiencies in the several cases considered have the following values:

- Carnot (constant temperature) = 0.56
- Otto and Langen free piston (constant volume) = 0.46
- Clerk (constant volume), with complete expansion = 0.56
- Clerk (constant volume), with incomplete expansion = 0.48
- Otto (constant volume) = 0.60
- Brayton (constant pressure), with complete expansion = 0.60
- Brayton (constant pressure), with incomplete expansion = 0.39
- Lenard (constant volume), with complete expansion = 0.20
- Lenard (constant volume), with incomplete expansion = 0.25

§ (47) PRACTICAL CONSIDERATIONS.—Thus the efficiency of the Carnot "Perfect" cycle is substantially greater than that of any of the others, while the Otto and Langen engine has an efficiency—when isothermal compression is realised—second only to that of the Carnot.

For the purposes of practical power production, however, it is not enough that a cycle should be of high ideal efficiency; in order that an engine may be practicable it is necessary, later after (1) that its cycle can be effectively performed in a very short time, and (2) that the ratio of mean effective pressure to maximum pressure shall be as high as possible. If (1) cannot be attained the engine can only run slowly, and is thus bulky and weighty in relation to the power developed by it. If (2) is not realised, then since the engine must be designed to withstand the maximum pressure developed it is necessarily weighty and costly relatively to its power output.

These two conditions have, so far, practically excluded all but the Otto, Diesel, and Clerk cycles, and it is of interest to determine in the several cases of § (40), the values of the maximum pressure, the mean effective pressure, and the ratio of these.

The mean effective pressure, \( P_m \), is the average height of the closed figure on the \( p_v \) diagram representing the useful work \( U \) (ft.-lbs.) done per cycle; if \( p_m \) be in lbs. per sq. in., and if \( V \) be the greatest, and \( v \) the least, volume (in cub. ft.) of the working substance, then

\[
U = \frac{144}{V - v} \text{ lbs. per sq. ft.} \quad \text{(72)}
\]

The maximum pressure developed will be denoted by \( P \), and in each case it is considered that the engine uses 1 lb. of mix. initially at atmospheric pressure \( p_0 \) of 14.7 lbs. per sq. in. and temperature \( t_0 = 300^\circ \text{C.}(\text{abs.)} \) where, by equation (12), its volume \( v_0 = 13.63 \text{ cub. ft.} \)

§ (48) MAXIMUM PRESSURE. THE CARBURET Cycle: Value of \( P_{max} \).—The calculation here is conveniently conducted as follows: As \( T = 2000^\circ \text{C.} \) and \( t_0 = 300^\circ \text{C.} \) we have, by equation (32), for the value of the adiabatic ratio \( \rho = (2000/300)^{2/5} = 104.36 \); thus the ratio of adiabatic expansion and compression must necessarily each have the enormously large value 104.36. The isothermal ratio \( r \) is arbitrary; if it be assumed as 2, then, by equation (30), the total expansion ratio becomes \( X = 2 \times 104.36 = 208.7 \); a value, it is necessary to point out, entirely out of the questions in any actual engine.

The maximum pressure \( P \) is obtained by aid of equation (12) and is given by

\[
P = \left( \frac{T}{t_0} \right) ^{X/\rho} \times 208.7 \times 14.7 \approx \text{about 20,450 lbs. per sq. in., or manyly 1,400 atmospheres.}
\]

Again, by equation (72),

\[
P_m = \frac{144V}{1 - (1/X)} \times \frac{c(T - t_0)}{\log \frac{P}{P_0}} \approx 96 \times 1700 \times \log 2 \approx 58 \text{ lbs. per sq. in.}
\]

so that the ratio of mean effective to maximum pressure is only 58/20,450, or about 1/350 of the point. Any such maximum pressure as 20,450 lbs. per sq. in. is of course entirely impracticable in practice, and it will also be observed that the mean effective pressure is only a small fraction of the maximum pressure. The cycle is entirely impracticable.

The design of an engine is dominated by the maximum pressure to be provided against; if we take this at the value adopted in the modern Diesel engine, viz. about 500 lbs. per sq. in. and also if the upper temperature limit be assumed at the low value of only 80° C. we shall have \( X = 13.65 \), \( \rho = 14.05 \), \( r = 1.26 \), and \( p_m = 0.1 \text{ lbs. per sq. in.} \) Thus even here the mean effective pressure in only 1/22nd of the maximum pressure, and has the limiting value of only 0.1 lbs. per sq. in. when the Carnot cycle is taken.

§ (49) The OTTO AND LANGEN "Piston" Cycle; RATIO OF \( P_{max} \).—See § (33) and Figs. 18 and 27. Here \( T = 2000^\circ \text{C.} \),
(30)

\[
\frac{p_1}{p_2} = \left(\frac{V_2}{V_1}\right)^\gamma, \quad \frac{p_1}{p_2} = \left(\frac{p_1}{p_2}\right), \quad \frac{p_1}{p_2} = \frac{p_1}{p_2}, \quad \frac{p_1}{p_2} = \frac{p_1}{p_2}, \quad \frac{p_1}{p_2} = \frac{p_1}{p_2}
\]

Thus the ideal cycle in this case requires a total expansion of 104-4 times the initial volume, and gives a mean effective pressure of only 1:026 lb. per sq. in., which is but 1/74th of the maximum pressure developed.

Moreover, in order to approximate even roughly to isothermal compression on the return stroke, it was necessary to run these free piston engines very slowly, and they were in consequence exceedingly cumbersome and unmanageable, but a trifling power relatively to their bulk and weight, notwithstanding their high theoretical efficiency.

A series of tests made by Clerk in 1885 on a 2-h.p. engine with a cylinder 121 in. in diameter showed that the maximum stroke was 40 in., and t.h.p. 2.9, with 28 explosions per minute, corresponding to a mean effective pressure of 12 lb. per sq. in.; the total expansion ratio attained was, however, only about 5.

The h.p. was 2.9, and the mechanical efficiency therefore 70 per cent. The consumption of coal gas was 24-6 cub. ft. per h.p. hour, corresponding to an (indicated) thermal efficiency of 0.11. Even this consumption, however, marked a notable improvement upon the results obtained with the earlier Lenoir and Hengy engines; the largest engine made of this very noisy free piston type was only of 3 h.p.

§ (60) The Diesel Cycle; Ratio of \(p_1/p_2\).--See § (41) and Fig. 15. Here

\[
\frac{p_1}{p_2} = 14.7 \text{ lbs. per sq. in.,}
\]

\[
v_1 = 1.5 \text{ c.i. cub. ft.,}
\]

\[
T_1 = 300^\circ \text{ C. (abs.),}
\]

\[
p_1 = 500 \text{ lbs. per sq. in. ;}
\]

\[
v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}
\]

Thus if the Diesel cycle in this case requires a total expansion of 104-4 times the initial volume, and gives a mean effective pressure of only 1.026 lb. per sq. in., which is but 1/74th of the maximum pressure developed.

Moreover, in order to approximate even roughly to isothermal compression on the return stroke, it was necessary to run these free piston engines very slowly, and they were in consequence exceedingly cumbersome and unmanageable, but a trifling power relatively to their bulk and weight, notwithstanding their high theoretical efficiency.

A series of tests made by Clerk in 1885 on a 2-h.p. engine with a cylinder 121 in. in diameter showed that the maximum stroke was 40 in., and t.h.p. 2.9, with 28 explosions per minute, corresponding to a mean effective pressure of 12 lb. per sq. in.; the total expansion ratio attained was, however, only about 5.

The h.p. was 2.9, and the mechanical efficiency therefore 70 per cent. The consumption of coal gas was 24-6 cub. ft. per h.p. hour, corresponding to an (indicated) thermal efficiency of 0.11. Even this consumption, however, marked a notable improvement upon the results obtained with the earlier Lenoir and Hengy engines; the largest engine made of this very noisy free piston type was only of 3 h.p.

§ (60) The Diesel Cycle; Ratio of \(p_1/p_2\).--See § (41) and Fig. 15. Here

\[
\frac{p_1}{p_2} = 14.7 \text{ lbs. per sq. in.,}
\]

\[
v_1 = 1.5 \text{ c.i. cub. ft.,}
\]

\[
T_1 = 300^\circ \text{ C. (abs.),}
\]

\[
p_1 = 500 \text{ lbs. per sq. in. ;}
\]

\[
v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}
\]

Thus if the Diesel cycle in this case requires a total expansion of 104-4 times the initial volume, and gives a mean effective pressure of only 1.026 lb. per sq. in., which is but 1/74th of the maximum pressure developed.

Moreover, in order to approximate even roughly to isothermal compression on the return stroke, it was necessary to run these free piston engines very slowly, and they were in consequence exceedingly cumbersome and unmanageable, but a trifling power relatively to their bulk and weight, notwithstanding their high theoretical efficiency.

A series of tests made by Clerk in 1885 on a 2-h.p. engine with a cylinder 121 in. in diameter showed that the maximum stroke was 40 in., and t.h.p. 2.9, with 28 explosions per minute, corresponding to a mean effective pressure of 12 lb. per sq. in.; the total expansion ratio attained was, however, only about 5.

The h.p. was 2.9, and the mechanical efficiency therefore 70 per cent. The consumption of coal gas was 24-6 cub. ft. per h.p. hour, corresponding to an (indicated) thermal efficiency of 0.11. Even this consumption, however, marked a notable improvement upon the results obtained with the earlier Lenoir and Hengy engines; the largest engine made of this very noisy free piston type was only of 3 h.p.

§ (60) The Diesel Cycle; Ratio of \(p_1/p_2\).--See § (41) and Fig. 15. Here

\[
\frac{p_1}{p_2} = 14.7 \text{ lbs. per sq. in.,}
\]

\[
v_1 = 1.5 \text{ c.i. cub. ft.,}
\]

\[
T_1 = 300^\circ \text{ C. (abs.),}
\]

\[
p_1 = 500 \text{ lbs. per sq. in. ;}
\]

\[
v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}, \quad v_1 = \text{?} \frac{p_1}{p_2}
\]
where, by equation (21),
\[ t_e = 408^\circ C, \]
and therefore
\[ v_e = \frac{96 \times t_e}{144 \times v_e} = 4.47 \text{ cft.} \]

Again, \( v_e = \frac{10.65 \text{ cft.}}{t_e} \)
and thus \( t_e = 4.20 \) (side equation 51).

\( T_2 \) is assumed at 1400° C, whence, by equation (25), \( v_e = 4.19 \) cft. ft., so that the total expansion ratio \( X = 0.4 \).

\[ p_e = \frac{96 \times t_e}{144 \times v_e} = 23.2 \text{ lbs. per sq. in.,} \]
and
\[ T = \frac{p_e}{v_e} = 925^\circ C \text{ (abs.).} \]

Hence, from § (30), \( U = 126-74 \text{ C.Th. U. of useful work, and accordingly, by equation (72),} \)
\[ p_e = \frac{126-74 \times 1400}{144 \times 37-47} = 33-0 \text{ lbs. per sq. in.} \]

The effective maximum pressure is \( (T - 147) \) lbs. per sq. in., = 55-5, which is only 1-68 times \( p_e \) — a very satisfactory feature of the cycle.

A test of a Brayton petrol engine of about 4 b.h.p., made by Clerk in 1878, showed a maximum pressure in the working cylinder of 47 lbs. per sq. in., a mean effective pressure of 50-2 lbs. per sq. in., and a consumption of petrol of 2-75 lbs. per b.h.p. hour, corresponding to the very low brake thermal efficiency of only 0.037.

\( T_2 \) is assumed at 1400° C (abs.), and therefore, by equation (22), \( v_e = 32-6 \) cft. ft.; then
\[ p_e = \frac{96 \times 1400}{144 \times 32-6} = 284 \text{ lbs. per sq. in. (abs.)} \]
and \( T = \frac{p_e}{v_e} = 718^\circ C \text{ (abs.)} \)

Hence
\[ U = k (T - T_2) - \frac{k}{v_e} (T - T_1) = 72-67 \text{ C.Th. U. of useful work.} \]

In this case, as the stroke of the piston in AK, we have to write
\[ p_e = \frac{1400 \times 72-67}{144 \times v_e} = 21.7 \text{ lbs. per sq. in.} \]

Thus the ratio of \( p_e \) to the maximum effective pressure of (98 - 147) lbs. per sq. in. thus here the satisfactory value 133-84: this engine failed commercially, however, on account of its excessively great consumption of fuel. Not only is the theoretical efficiency of the cycle low, but even this low efficiency was not nearly attained in practice. The engines were built in sizes of from one-half to three horse-power. An experiment by Tresca on a one-half horse-power engine showed a consumption of 95 cuf. ft. of (Paris) coal gas per b.h.p. hour, which is fully eight times as great as that of a modern four-stroke gas engine of moderate power.

§ (54).—Collecting the results obtained in the preceding paragraphs for comparison, we have the following for typical engines, each using 1 lb. of air, and working between the absolute temperatures 2000° C. and 500° C.:

*With complete expansion.

The modern Diesel engine consumes only about 0-45 lb. of oil fuel per b.h.p. hour, corresponding to a brake thermal efficiency of fully 0-30.

§ (53) THE LEONHARD CONSTANT VOLUME CYCLE: VALUE OF \( p_e \)—See Figs. 17 and 20 and §§ 32 and 42. Here also
\[ p_e = 14-7, \]
\[ v_e = 13-6, \]
\[ t_e = 300^\circ C, \]
\[ T = 2000^\circ C \]
so \( p_e = 08 \) lbs. per sq. in. (abs.).

The relative values and advantages of the various cycles are very fully discussed by Clerk in *The Gas, Petrol, and Oil Engine* (Longmans), vol. i., 1900.

§ (65) LOSSES IN INTERNAL COMBUSTION ENGINES.—In all that precedes it has been assumed that the working substance—air—regarded as a perfect gas—and that the conditions are such that each cycle can be perfectly carried out. This is impossible in actual practice, and is due mainly to the following causes:

(1) The working gases lose heat to the surfaces of the combustion chamber, cylinder,
and piston drawn during and after explosion by radiation and convection.

(2) The unexplained charge is usually heated on entering the cylinder, with consequent expansion and reduction of the mass of charge exploded.

(3) In constant-volume cycles the explosion is never instantaneous, as assumed in theory.

(4) The working substance is not dry air, but a mixture of nitrogen, carbon dioxide, steam, and oxygen, having specific heats which are not constant, but increase with rise of temperature.

(5) The working substance is changed in volume by combustion, so that the volume which is heated and expanded differs from that which is compressed when measured at the same temperature and pressure.

(6) Combustion is not complete when maximum temperature is attained, and is even, in some cases, not complete at release.

(7) Some throttling or "wire-drawing" always occurs during admission, and there is always some degree of back pressure opposing the exhaust.

(8) The working gases lose heat to the cylinder walls during compression.

These several sources of loss may be considered in some further detail.

§ (58) Loss of Heat to Walls during Explosion and Expansion.—The physical properties of case iron, of which the cylinders of all internal combustion engines, excepting only air-craft engines, are made, renders it necessary that they shall be kept cool either by a water-jacket or, as in many small engines, by a stream of cold air passing over heating-radiating gills formed on the outer surface of the cylinder. In practice it is found that 25 per cent to 30 per cent of the whole heat evolved by the combustion of the working fluid is lost in this way alone. The highly heated gases lose heat to the containing surfaces partly by radiation, and, being in a state of very violent turbulence, also by convection.

The general rule that the better the absorber the better the radiator, and the principle that a perfectly transparent substance, whatever its temperature, could radiate no energy, lead to the conclusion that gases in chemical equilibrium—which then possess nearly perfect transparency—can emit no appreciable radiation.

When radiation does take place from gases it appears to arise from the flame due to chemical action proceeding in the gas, and in internal combustion engines any radiation from the flaming mixture is absorbed by the enclosing metal walls of the combustion chamber, cylinder barrel, piston crown, and valve heads, wherein it appears as sensible heat, which is then conveyed by conduction to the jacket and surrounding air. Loss of energy by radiation, in this connection, was first considered by Calender in 1906. Tests by him on coal-fired engines showed that the loss of heat per cycle could be represented approximately by an expression of the form 
\[ q = a + bT, \]
where \( T \) is the time of one revolution, and \( a \) and \( b \) are constants. Radiation loss from the burning gases proceeds with very great rapidity near the instant of maximum temperature, and this practically instantaneous loss may be considered as represented by the constant term 
\[ a. \]
The second term 
\[ bT \]
represents a loss by radiation and convection—conduction proportional to the time during which the cylinder surfaces are exposed to the burning gases.

§ (57) Radiation from Flames.—R. v. Helmholtz found, when using a "solid" flame of about 1 in. in diameter, that a hydrogen flame radiated about 3 per cent, coal gas about 5 per cent, and CO about 8 per cent of its total heat of combustion. These were very small flames. A large flame radiates more energy per unit of area, since a flame is largely transparent even to its own radiation, and thus radiation is received not only from the surface molecules, but also from all those behind it. Calender, repeating some of Helmholtz's experiments on a larger scale, found that the radiation from a luminous non-luminous coal-gas flame 1-2 in. in diameter may amount to as much as 15 per cent of the whole heat of combustion. Experiments made by Julins on different kinds of flame have shown that the radiation is almost wholly due to the CO and \( 1_{2}O \) (steam molecules). The explosion of gases in an exhaust vessel, or a gas engine cylinder, differs considerably from any open flame in respect of radiation, as not only is the density of the gas much greater in the closed vessel, but it is also more mixed by mixture with the outside air. Hopkins (1919) made experiments on the radiation emitted during explosion and subsequent cooling of a mixture of 0-15 coal gas and 0-85 air, by volume, in a closed vessel. He found that the total heat radiated during and after the explosion amounted to over 22 per cent of the whole heat of combustion. The radiation up to the instant of maximum pressure amounted to 3 per cent, and continued at a diminishing rate for a considerable period thereafter. It was still perceptible 0-5 second after maximum pressure, when the gas temperature had fallen to 1060°C.

§ (56).—The conditions existing within a gas engine when working have been vividly described by Clark, who fitted a cylinder with a stout observation plug of glass. He says: "While the engine is at work, a continuous glare of white light is observed; a look into the interior of a boiler furnace gives a good
motion of the flame filling the cylinder of a gas engine." The loss by radiation from the flaming mixture will be greater as the absorbing power of the containing metal surfaces is increased. Hopkinson has coated the interior of an explosion vessel with tin-foil, and compared the results obtained by exploding mixtures of identical composition, firstly with the tin-foil highly polished, and secondly with its surface covered with lamp-black. He found that nearly the same maximum pressure was developed in both cases, but that the fall of pressure during cooling was considerably less with the bright than with the black surface. Further bolometric experiments by Hopkinson consisted in covering a small portion of the inner surface of an explosion vessel with thin copper strip (1) highly polished, (2) blackened, and (3) with the strip protected from direct contact with the flame by a plate of rock-salt. It was found that the rate of increase of temperature of the blackened surface during explosion and the subsequent early stages of cooling greatly exceeded that of the polished strip, the difference between them being roughly equal to the rate of temperature increase observed when the strip was covered by the rock-salt, which transmitted upwards of 90 per cent of the radiant energy to the strip while protecting it against any direct gain of heat by contact with the flaming gas.

Using a mixture of 0-15 coal gas to 0-85 air, by volume, giving a maximum temperature of 2150° C., Hopkinson estimated from these experiments that the loss of heat by radiation to the enclosing surface up to the instant of maximum pressure, was about 8 per cent of the whole heat of combustion, and that radiation continued during cooling certainly down to 1000° C. If combustion were complete at the instant of maximum pressure, which is also that of maximum temperature in closed vessel experiments, it would follow from the observed greater loss of energy by radiation during explosion to the black than to the bright surface, and the observed equality of the maximum temperatures attained in each case, that the internal energy of the gas at the same temperature would be greater when the enclosing surface was bright than when blackened. Clark has shown, however, that combustion is never complete at the instant when maximum temperature is attained, and finds that in gas engine practice in general only some 86 per cent of the heat is evolved at this instant, the remaining 14 per cent appearing during a period, at least, of the expansion working stroke. Combustion is usually practically complete when release takes place; with weak mixtures, or badly-designed combustion chambers, combustion may be markedly incomplete even at release.

§ (50) CYLINDER TEMPERATURES.—Although the maximum temperature of the working gases is of the order of 2000° C., the mean temperature at the inner surface of the metal of the cylinder never exceeds a quite moderate value of, at most, some 200° C. above that of the cooling water in large gas engines; in the thin walls of petrol engine cylinders the difference is much less, and is usually below 50° C. Hopkinson placed patches of tin-foil on the inner surface of the combustion chamber of a gas engine cylinder 11½ in. in diameter, and found these were quite unaffected by the successive explosions, although the heat-flow rate in here a maximum, and the melting-point of tin only 230° C. In this connection it is also of interest to record that, using a rich mixture (1 : 9) of coal gas and air, he found at the instant of maximum pressure in a cylindrical explosion vessel about 214 in. diameter x 27 in. long, large differences of temperature at different points within the vessel. The following are his results:

- Temperature at centre of volume of the vessel, near point of ignition of the mixture: 1000° C.
- Temperature at 4 in. from wall of vessel: 1700° C.
- Temperature at 0-4 in. from wall at end of cylinder: 1360° C.
- Temperature at 0-4 in. from wall at side: 860° C.

A rough approximation to the rate of heat-flow per unit area from the gases to the cylinder surfaces is obtained by dividing the mean area exposed to the heated gases into the total heat appearing in the jacket water plus that lost by ordinary external radiation from the engine as a whole.

Comparing in this way a 35 h.p. four-cylinder 4-62 in. diameter x 5-08 in. stroke Siddeley petrol engine running at 930 revs, per minute, with a 40 h.p. single-cylinder 11½ in. x 21 in. Crossley gas engine running at 180 revs, per minute, Hopkinson 1 obtained the following results:

<table>
<thead>
<tr>
<th>Item</th>
<th>Crossley</th>
<th>Siddeley</th>
</tr>
</thead>
<tbody>
<tr>
<td>C.T.U. lost per minute to jacket water, and by general external radiation</td>
<td>2250</td>
<td>2300</td>
</tr>
<tr>
<td>Percentage of ditto to total heat supply</td>
<td>34-0</td>
<td>40-6</td>
</tr>
<tr>
<td>C.T.U. lost per cylinder per minute</td>
<td>2250</td>
<td>276</td>
</tr>
<tr>
<td>Heat-flow in C.T.U. per sq. in. of exposed surface per minute at---</td>
<td></td>
<td></td>
</tr>
<tr>
<td>In-centre</td>
<td>0-5</td>
<td>7-0</td>
</tr>
<tr>
<td>Out-centre</td>
<td>2-05</td>
<td>3-7</td>
</tr>
<tr>
<td>Mean</td>
<td>3-2</td>
<td>6-85</td>
</tr>
</tbody>
</table>

Thus the maximum heat-flow rate did not exceed 7 C.T.U. per sq. in. per minute, and the temperature-grade necessary for this rate through cast iron is only about 100° C per in. of thickness. As the walls of the Siddeley engine cylinder were only \( \frac{1}{3} \) in. thick, Hopkinson points out that the mean temperature of the internal metal surface, where water-jacketed, never exceeded that of the jacket water by more than about 30° C. The walls of the Crossley engine cylinder were almost four times as thick as the in the Siddeley, which would correspond to a mean temperature of inner surface of, at most, 125° C above that of the jacket water, or about 200° C actual temperature.

§ (60) PISTON AND VALVE TEMPERATURES.---
The pistons and valves of internal combustion engines are rarely water-cooled, and consequently become very hot, their heat having to be conducted through some distance before reaching the jacket water. When working at full load, Hopkinson found in the Crossley engine above cited temperatures at the centres of the piston crown and exhaust valve about 510° C. For the gas engine mixture used by him the temperature of pre-ignition was slightly above 700° C. With oil engines when run at full load pre-ignition usually soon occurs, and is commonly prevented by the injection of a water-spray into the cylinder during explosion.

In the preceding remarks it has been assumed that the internal metallic surfaces exposed to the heated gases are clean; actually the combustion chamber surface is quickly covered with a deposit of carbon, while the working barrel of the cylinder is coated by a thin film of oil. The carbon deposit on the combustion chamber surface and piston crown increases the loss by radiation from the flaming gases; by polishing the surfaces of the combustion chamber and piston of a gas engine a perceptible increase in mean pressure has been obtained. Again, a thick deposit of carbon, especially on the hot piston crown, by its low conductivity may create intersegment points or patches, and thus cause pre-ignition; thus carbon deposit is obviously to be avoided as far as possible.

§ (61) RADIATION LOSSES.---Clark (Gustave Caen Lecture, 1913) states that radiation losses increase very rapidly with temperature difference; the loss being approximately proportional to the difference of the fourth powers of the absolute temperatures of the gas and inner wall surface respectively—agreeably with Stefan's Law. He states also that radiation increases with increase in the dimensions of the containing vessel; and he points out that Stefan's Law practically limits the temperatures attainable in gas-engine practice.

§ (62) HEAT-FLOW.---Reference may be made to the fifth report of the Censorial Explosives Committee of the British Association (Dundee, 1912), which contains a valuable resumé of present knowledge relating to heat-flow from the working gases into the cylinder walls of internal combustion engines.

The general conclusions reached are, briefly:

(i.) The rate of heat-flow from gas to walls is greatest at maximum temperature and pressure, and rapidly diminishes as the piston performs its outstroke; the greater part of the heat-flow has occurred in a comparatively short time, and when the piston has moved but little from its position. Hence the bulk of the heat lost by the gases to the cylinder passes into the combustion chamber, piston crown, and valve heads, and but little is received by the working barrel. Clerk has calculated that the actual rate of heat-flow in the first \( \frac{2}{3} \)ths of the outstroke is equal to six times that of the whole stroke, in ordinary gas engines, when working at full load. If piston be water-cooled, in considering the cooling of the cylinder it is probably sufficient to neglect altogether the heat-flow into the outer half of the working barrel. When pistons are uncooled a water-jacketed barrel is needed mainly to keep the piston cool.

(ii.) The temperature-gradient necessary to maintain the required rate of heat-flow from the inner surface of a combustion chamber to the jacket water rarely exceeds 60° C per in. and for such surfaces, kept fairly clean, effective cooling presents no great difficulty. At special points, e.g., the centre of the piston crown (when uncooled) temperature is high; with a four-stroke engine of 24 in. cylinder diameter a temperature of almost 100° C may be found here. With large gas engines the necessary great thickness of the combustion chamber walls, and the practical difficulties of ensuring free circulation of jacket water everywhere may result in the formation of high local internal surface temperatures.

(iii.) An important effect of radiation is the greatly increased heat given to cylinder walls when mean pressure is increased by increasing mixture-strength; the metal temperature and jacket-water temperature are raised in much greater degree than the fuel consumption, and efficiency is diminished. In large engines this sets a practical limit to power output which, if exceeded, results in rapid overheating of the engine.

(iv.) Another important effect of radiation is the greatly increased heat received by the walls from a large than from a small volume of gas; it results from this, that the difference between the efficiency of a large and a small engine is lessened, and also that the difficulty of adequately cooling very large engines is increased beyond that arising from the neces-
sary great thickness of the cylinder walls by the increased amount of heat received through radiation from the greater volume of glowing gas enclosed.

(v) Effect of Density.—The density of the gas in an internal combustion engine of the Otto-cycle type is from four to seven or eight times that of the atmosphere; in Diesel-cycle engines it is considerably greater; increase in density greatly increases heat-flow as compared with an ordinary closed vessel explosion with atmospheric density before ignition. The total heat lost to the jacket water is found to increase with the density, but not quite in simple proportion; the exact relation seems to be complex, and is not ascertained; it is probable that the combined convection and radiation heat losses in a vessel of given form can be fairly well expressed as increasing according to some fractional power of the density.

The question as to the best compression ratio to adopt is closely connected with that of density. When compression is increased by reducing the volume of the combustion chamber, not only is the density of the gas, and therefore the total heat loss, increased, but the area of enclosing surface is also reduced, and hence the rate of heat-loss per unit of area is increased by both causes combined. Though efficiency is increased in theory by increase of compression ratio, this increase may be more than annulled by the increased heat-loss to the enclosing walls, and there is thus a value of the compression for which the efficiency practically attainable is a maximum. But it may easily happen that even before this maximum efficiency is attained the increased rate of heat-flow per unit area of enclosing walls may give rise to cooling difficulties and pre-ignition trouble.

The cause of pre-ignition is commonly the overheating of some point or patch of the metal, or carbon deposit therein, due to excessive heat-flow following increased density. If the enclosing metal surfaces could be kept clean and cool, compression ratios could have much higher values than are at present practicable.

§ (63) HEATING BEFORE COMPRESSION.—In large gas engines the ratio of surface to enclosed volume of gas is relatively small, while the thickness of the cylinder walls is necessarily great. In order to avoid setting up dangerous stresses in the metal through heating, it is found necessary to keep the jacket cold by arranging for the circulation of a ample supply of cooling water; the temperature on leaving the jackets, in large gas engines and Diesel engines, is usually between 30° C and 60° C. In very large gas engines the pistons and valve heads are also water-cooled, and in these engines, therefore, the temperature of the whole enclosing surfaces of combustion chamber, piston, etc., is always low. In the much larger class of gas engines with uncooled pistons and valves, the average temperature of the piston crowns and valve heads is very much greater. In the exceedingly large class of small quick-revolution internal combustion engines of the petrol type, the jacket water temperature is usually between 90° C and 100° C, while in air-cooled engines of this class, the mean temperature of the whole cylinder is considerably above 100° C, and the pistons and valve heads correspondingly higher.

In every case, when a fresh charge is taken into the cylinder, some increase in its temperature is caused by the higher temperature of the enclosing surfaces; in addition, in the three practical cycles of Clerk, Diesel, and Otto, there is always some high temperature burnt gas from the previous cycle remaining in the combustion chamber at the end of exhaust with which the entering fresh charge mixes, and by which its temperature is always raised. From these two causes, the fresh charge is always heated at the beginning of compression, and in the Otto cycle gas engines of the smaller type, and petrol engines, a temperature of 200° C at this point is not unusual. The rise of temperature results in a lessened density of fresh charge taken in, and the mass of fresh charge is further reduced by the presence of residual burnt gases in the combustion space; part from any effect of this upon thermal efficiency the heat evolved per cycle is lessened, and the power output of the engine correspondingly reduced.

§ (64) THE DIESEL CYCLE; EFFECT OF HEATING BEFORE COMPRESSION.—Consider the case taken in § (63), with \( p_1 = 14.7 \) lb. per sq. in. (abs.), and \( r_1 = 134 \) cuh. ft. (abs.), the volume at atmospheric. But, due to heating on admission, suppose \( T'' \) (Fig. 15) to be 400° C (abs.); then at K we have \( 14.7 \) cuh. ft. of air at pressure 14-7, and temperature 400° C, i.e. the mass of the charge is reduced from 1 lb. to 0.75 lb., and the value of the constant \( R = \frac{p_1 T''}{R} \) is now 72. The volume of the combustion chamber remains unaltered at 14-2 cuh. ft., and hence \( p_2 \) is also unaltered at 6000 lb. per sq. in. (abs.). But \( T_2 = \frac{p_2 r_2}{R} \) is now increased from 833° C to 1111° C (abs.). Hence as, by assumption, the maximum temperature \( T \) remains unchanged at 2000° C, we have \( v_2 = \frac{T''}{T} \) or \( v_2 = 2.002 \) cuh. ft., whereas \( v_1 \) is now reduced from 2 to 1-8, and accordingly, agreeably with equation (53) the thermal efficiency increases. Again, \( T_2 = \frac{p_2 r_2}{R} = 1 \cdot 7 = 015^\circ C. \) Instead of 1043° C; the efficiency, by equation (62), is therefore now increased from 0-65 to 0-83. But the heat converted into useful work has been reduced by the reduction of the charge thus.
In this cycle increasing the lower limit of temperature \( T_1 \), increases the compression temperature \( T_2 \) in the same proportion; hence \( t_2 \) approaches more nearly to \( T \), and accordingly the constant pressure expansion ratio \( e \) is reduced with consequent increase in the adiabatic expansion ratio and reduction of the pressure drop at the release point \( H \). The efficiency is increased from 0-55 to 0-69, but owing to the smaller expenditure of heat the power output of the engine is reduced in the proportion of 100 to 103.

**Case (ii).—In this case the efficiency is also, in theory, multiplied, and the temperature of the working substance is only increased by a relatively small amount during the adiabatic compression period: the practical reduction of efficiency may hence be expected to be smaller in this case. The mass of the charge is reduced, as before, to \( \frac{3}{4} \) lb., but the heat supplied is also reduced, and is given by \( H = \frac{75}{36} \left( \frac{800}{600} - \frac{800}{400} \right) = \frac{36}{36} \) C. Th. U. instead of 88-67. The mean effective pressure, at unaltered efficiency, now drops to 60 lb. per sq. in., and the engine output is now represented by the number 042 only.

Thus in Otto-cycle engines, heating the incoming charge does not, in theory, affect the efficiency, though in practice some loss of efficiency results from increased heat losses to the cylinder. The reduction in the mass of the charge, with consequent reduction in the heat supply, results, however, in a rapid falling off in the output of power.

**§ (68) Time of Explosion.**—In the preliminary simple theory of the internal combustion engine constant volume cycle, explosion is assumed to occur instantaneously; actually a small, but finite, interval of time elapses between the instant of ignition and that at which maximum pressure is attained. The time of explosion in constant volume experiments may be defined as the interval of time between the commencement of increase of pressure and the attainment of maximum pressure.
As the mixture richness is increased a point is, however, soon reached at which the time of explosion is a minimum; the following figures from experiments by Clerk, and the Massachusetts Institute, Boston, illustrate this:

<table>

On the passage of the igniting spark the gas in its immediate vicinity is instantly inflamed with accompanying sudden expansion; the inflammation very quickly extends outwards in all directions, the inflamed portion rapidly compressing, and thus heating, the uninflamed portion. Parts of the inflamed gas are also projected into the uninflamed volume, and thus cause the general inflammation to proceed at an increasing rate nearly up to the point when complete inflammation is attained. It is clear, therefore, that the time of explosion will be greater as the volume of gas exploded is greater, and also that it will be lessened by having more than one point of ignition, provided the additional ignition points are effective. Further, if a considerable volume of the gas be ignited at once, by a long and powerful spark, or a large flame, the time of explosion will be reduced; a small separate chamber connected with the main explosion vessel if filled with explosive mixture, and ignited, will project a rush of flame into the main vessel and so much reduce the time of explosion. The shape of the explosion vessel has also a marked influence, and has also the position within the vessel of the point of ignition. This latter point is well illustrated in Bairstow and Alexander’s experiments, using a cylindrical vessel 10 in. diameter x 18 in. long, with the ignition point situated at different points.
The maximum pressure attained was, in each case, roughly 220 lbs. per sq. in. (abs.), and the explosion was most rapid when the mixture was fired from the centre of the cylinder. Though rapid ignition does not cause any increase in the maximum pressure attained, it is yet of importance in internal combustion engines in order to avoid loss of work from a comparatively slow pressure rise upon a rapidly moving piston. Accordingly in large gas engines, and in the petrol engines of racing cars, it is common to find two or even more igniting points per cylinder. In the case of a petrol engine tested by Professor W. Watson, for example, it was found that with single ignition the time of explosion was 0.0055 second, and that this was reduced by almost one-third, viz. to 0.0037 second when double ignition was used. Increased power was obtained when using double ignition, the advantage gained being greater as the revolution speed increased, as the following figures show:

<table>

\( \textit{\S} (67) \text{Turbulence.} \) At an early date it was observed by Clerk that gas engines would have been impracticable, through necessarily slow running, had not the rates of explosion been as great in actual engine cylinders as in closed vessel experiments. In the case just cited, the time of explosion of the petrol air mixture in an actual engine was only 0.0055 second, whereas the shortest explosion time obtained in the Boston experiments—albeit with a larger vessel—was 0.0053 second, or more than ten times as great. In larger gas engines also the same result is observed; Fig. 30 is a reproduction from a diagram taken by Humphrey during a test in 1000 h.p. Premier engines using Monel gas. The cylinder was 28 inches in diameter and the stroke 30 in.; the average revolution speed was 1280 per minute. The diagram shows that maximum pressure was attained when the piston had moved forward only about \( \frac{1}{3} \) of the outstroke, corresponding to a time interval of only 0.0426 seconds, which is, in this case, substantially the time of explosion. Thus even in this large cylinder the time of explosion is only about one-hundredth as great as was observed in the closed vessel end-gas experiments above cited.

This feature has recently received special attention, and Clerk found in some experiments carried out in 1912 that the time of explosion in the same engine diminished with increase in the revolution speed, and that this resulted mainly from the increased rate of inflammation caused by the violent turbulent motion set up by the sudden rush of the fresh charge into the cylinder during the suction stroke, and which persisted during compression; in gas and petrol engines during the suction stroke the average velocity of the entering fresh charge through the inlet valve is from 100 to 120 ft. per second.

Clerk \(^3\) has carried out further experiments showing very strikingly the important part played by turbulence in reducing the time of explosion in actual engines, and thus rendering high revolution speeds practicable. He took indicator diagrams from the same engine: (1) firing the charge in the usual manner, and (2) firing the charge after compressing and expanding it during one or two revolutions of the crank-shaft, thus giving time for the turbulence to largely subside. Comparison of the diagrams so obtained shows at once that the effect of damping down turbulence was to retard the rate of inflammation to a remarkable extent, completely changing the form of the diagram.

Two of the diagrams so taken are shown in Figs. 31 and 32; the time of explosion with normal ignition, from A to B, is 0·377 and 0·33

\(^{3}\) Max. \( \text{pw} \) occurs at B.
explosion increases to 0.02 and 0.08 seconds respectively. The cylinder was 9 in. in diameter, with 17 in. stroke, and was run at 180 revolutions per minute under full load conditions with jacket water at 70° C. Two electric igniters were fitted, one in the inlet port at the back of the combustion chamber, the other at the side of the cylinder just clear of the piston, when fully "in." It will be noted that in this case the explosion is more rapid with the side igniter, and that in both cases the time of explosion with partly quenched turbulence is about 2½ times as great as under normal working conditions with undamped turbulence.

Thus, due to turbulence, the time of explosion in the actual engine was only 4th to 5th that observed in the closed vessel explosion experiments of Clerk and Hopkinson, with the mixture at rest, and internal combustion engine, the working substance after ignition consists of a mixture of nitrogen, steam, carbon dioxide and frequently a small amount of free oxygen. When the chemical formula of the fuel or "carburetted" is known, the heat evolved during combustion may be readily calculated. In Table I, some physical constants are given for the substances involved in Internal Combustion Engine practice.

In Tables II. and III. the quantities of heat evolved in the complete combustion of 1 lb. and of 1 cub. ft., of various gases, etc., are given.

§ 68.—From Tables II. and III. it will be noted that a hydrogen-air mixture contracts after combustion to 0.863 of its initial volume, with corresponding reduction in the pressure developed. Further, notwithstanding the very high calorific value of hydrogen per lb., its excessive bulkiness results in a heat evolution of only 30.8 ft. lbs. per cub. ft.

* As 1 cub. ft. of carbon (as gas) forms 2 cub. ft. of CO₂, and also 2 cub. ft. of CO₂ it follows that—in the formation of 1 cub. ft. of CO₂, 270 C.T.U. are evolved; and in the formation of 1 cub. ft. of CO₂, 270 C.T.U. are evolved.

With annual average of "hot" and average petrol above, Table II, gives the approximate amount of heat evolved by the combustion of 1 cub. ft. of petrol, at 60°F., and atmospheric pressure of 14.7 lbs. per sq. in. Other gases and hydrogen mixtures used for test purposes, are given in Table II, C.T.U. of various gases per cub. ft.

- Environments: Engines, Thrudanamics of Internal Combustion, Explodability of mixture with air at 0°C. and atmospheric pressure.
- Hydrogen-air mixtures are very simple to ignite, but hydrogen is highly explosive in air and hydrogen-air mixtures are dangerous to use.

hydrogen, as, e.g., coke oven gas, pre-ignition trouble is often experienced. Clerk has entirely overcome this by diluting the fresh charge, from 10 per cent to 20 per cent, by volume, of cooled exhaust gases. By this means, the free oxygen is reduced and replaced by a mixture of carbon dioxide and nitrogen, any mixture of known composition could be readily calculated—apart from heat losses to the containing vessel—provided the heat of the mixture were accurately known.

The total mass of the charge is maintained, while the addition to the inert gases reduces its inflammability, and thus prevents the occurrence of pre-ignition even in sustained heavy load running.

For a small range of temperature, as from 0° C. to 200° C., the specific heats of the ordinary "permanent" gases are roughly constant in value, and are given in Table VI.

Consider, for example, 1 cub. ft. of CO₂-air.

mixture at 0° C. and atmospheric pressure. From column 6 of Table IV, this evolves on combustion 55-6 C.T.U. of heat. Also, from Tables I and IV, its mass is given by 0.294/17.78 + 0.769/12.387 = 0.8 lb., while from kinds all agree, however, in showing that no such high temperature as 430°F (abs.) is ever even approached; and that, in general, the maximum temperature (and consequently pressure) realised in constant vessel, there would be attained a maximum temperature T and pressure p (both abs.), such that 55-6 = 0.8 x 17 x (T - 273), whence 

\[ T = 430° F. \text{ (abs.)} \]

\[ T = 430° F. \text{ (abs.)} \]

whence \( p = 236 \text{ lbs. per sq. in. abs.} \)

\[ V = \frac{p}{T} \]

\[ V = \frac{p}{T} \]

Table VI. It is clear that \( Z \) may be taken at the value 0-17 C.T.U. per lb. for the mixture. If, then, this 1 cub. ft. of CO-air mixture is exploded at constant volume, with \( Z \) constant in value at 0-17, and no heat loss to the containing volume explosion experiments is, roughly, about one-half only of that indicated by calculation made in the manner as just illustrated. Thus Table VII, contrasts actual with calculated temperatures and pressures from constant volume experiments by Clerk with Oilsman coal-gas-and-air mixtures initially at 200° C. (abs.), and 14-8 lbs. per sq. in.

With reference to the figures given in column 2, which are calculated from the actual maximum absolute pressures attained (column 1) by aid of the formula \( T_{p_{a}} = p_{a}/p_{p_{a}} \), it may be observed that these do not give the highest temperatures existing at the instant of maximum pressure, but are merely averages. There is a hot nucleus of gases at considerably higher tem-
temperature than those of the portions nearer the cooling-cooling walls—ashes recently pointed out in § (90); the figures given in column 2 closely approximate, however, to the mean "maximum" temperatures actually attained.

§ (72) Variation of Specific Heat.—The characteristic equation of an ideally perfect gas is

\[ pV = nRT \ldots \ldots (12) \]

where \( R \) is the difference of the constant specific heats, \( k_p \) and \( k_v \), and is therefore also a constant.

But this equation is true for any fluid whereof the specific heat \( k_p \) is a function of the temperature only, provided that the difference of the two specific heats remains constant, and such a fluid will obey Boyle's Law exactly at all temperatures; this, however, will only be true if both \( k_p \) and \( k_v \) are independent of the density of the fluid.

Joly found both for air and CO₂ that \( k_p \) appeared to increase slightly with density; thus in the case of CO₂:

<table>
<thead>
<tr>
<th>At Pressure, Lbs./sq. in. Abs.</th>
<th>Density (Water = 1)</th>
<th>( k_p )</th>
<th>( k_v )</th>
</tr>
</thead>
<tbody>
<tr>

<td>-384</td>
<td></td>
</tr>
<tr>
<td>330-5</td>
<td>-0373</td>
<td>-178</td>
<td></td>
</tr>
</tbody>
</table>

an increase of about 3 per cent only. In the case of hydrogen the specific heat appeared to decrease slightly with increase of density. The variation with density has, as far, been treated as negligible, and experimentally obtained values of specific heat at various temperatures are reunited by empirically found functions of temperature only.

§ (73) Relation between \( k_p \) and Temperature.—Regnault examined the relation between \( k_p \) and temperature in the case of air and CO₂, and formed the conclusion that between -30° C and +200° C, the specific heat of air remained sensibly constant, while that of CO₂ increased by nearly 18 per cent.
These results indicate substantial increases in $k_p$ with rise of temperature for all the three gases. Holborn and Austin have also calculated the value of $k_p$ for CO$_2$ at temperatures from 0°C to 800°C from their own results and also from those of Langen and Mallard and Le Chatelier's experiments. The figures are given hereunder:

### Table X

VALUES OF $k_p$ FOR CO$_2$ FROM 0°C TO 800°C (O.RINARY)

<table>
<thead>

Thus 1 cuf. ft. of the mixture, measured at 0°C and atmospheric pressure, weighs 0.978 lb. and agrees well with Table VI. Should have a specific heat $k_p$ between 0°C and 200°C of 0.14567 C.Th.U. or, in work units, 20.38 ft.-lbs.; thus the experimental and calculated results agree very well.

After explosion the ordinary working stroke was performed, but instead of return taking place near the end of the stroke, both valves were kept closed while the crankshaft continued to revolve through the momentum of the engine fly-wheel, thus alternately compressing and expanding the entrapped mixture. An indicator diagram was taken, recording the changes of volume and pressure undergone by the gases.

The gain of internal energy by the mixture during compression from any point A to B (Fig. 33) is equal to the external work (MAHN) done upon the mixture in compressing it minus the heat lost to the cylinder walls in the interval; while during any expansion period, and generally, the loss of internal energy is equal to the external work (MBEN) done by the mixture in expanding from B to C, plus the loss of heat in the cylinder walls.

The external work is readily obtained with considerable accuracy by planimetric measurements of the diagram, while the changes of temperature can be calculated from

* Compare with column 8 of Table VI.

simultaneous values of $p$ and $v$ taken from the diagram, by aid of the relation $p(V-p) = T\theta$, provided the temperature $T$ at any one point

of the diagram be known. The loss of heat to the cylinder walls was estimated by a comparison of the compression curve with the immediately following expansion curve on the assumption that the total heat lost by the mixture during any, the same, part of the stroke is the same during expansion as during compression for the same mean temperature.

Clerk expresses the Apparent Specific Heat, $\theta$, thus deduced, in ft.-lbs. per cuh. ft. of mixture at $0^\circ$ C. and atmospheric pressure; the corresponding values in C.T.B.U. per cuh. ft. are added in Table XI. His results are very closely resumed by the equation

$$\theta = \frac{dH}{dV} = q(1 - be - \lambda T)$$  (73)$$

where $a$, $b$, and $\lambda$ are constants, and $T$ is the absolute temperature in $^\circ$ C. It will be found that $\lambda = 28$, $b = 6$, and $\lambda = 00186$.

For purposes of computation equation (73) is more conveniently written

$$\Theta = \frac{1 - b_T}{28} = -0.30103$$  (73)$$

and values calculated from this equation are given in column 6 of Table XI, for comparison with those experimentally determined. The empirical equation (73) makes $\theta$ increase from 14.0 at the absolute zero of temperature, to an asymptotic value of 28.0 when $T$ is infinite.

§ (75).—Integrating equation (73) gives for the increase in internal energy in this case, from temperature $T_0$ to temperature $T$,

$$H - \Pi_0 = q(T - T_0) - \frac{p_T}{T_0} (e^T - e^{-1})$$  (74)$$

On, $\kappa$, $\kappa_T$ being values of the apparent specific heats at $T$, $T_0$, respectively.

By aid of this equation, and of equation (73), Table XIa has been calculated, giving values of $\kappa_T$ for this gas-engine mixture at every 100 degrees from $0^\circ$ C. to $2500^\circ$ C., together with values of the internal energy ($H - \Pi_0$), in ft.-lbs. per cuh. ft. at $0^\circ$ C. and atmospheric pressure, relatively to $0^\circ$ C. as an assumed zero.

On p. 20 of the 7th Report of the Gas Explosions Committee of the British Association (1814), a curve is given showing the variation of internal energy with temperature for this mixture. This curve is considered to be more reliable and based on the most reliable experimental results available; it is reproduced in Fig. 33A. For

</tbody>
</table>

On the curve is shown also the curve obtained by plotting ($H - \Pi_0$) against $T$ from the figures given in Table XI. It will be seen that the two curves agree very well from $0^\circ$ C. to $1000^\circ$ C., but that at temperatures above $1000^\circ$ C. the Committee’s curve rises somewhat abruptly above the other. The curve of equation (75)’s results from Clerk’s
The mean value of \( k_v \) between \( T_0 \) and \( T \) is

\[
H - H_0 = \frac{1}{R} \left( \frac{p_v}{v} - p_0 v_0 \right) \left( k_v - k_{v0} \right) + \int_{v_0}^{v} \frac{pdv}{v}.
\]

As \( p, v, p_0, v_0 \), and \( \int_{v_0}^{v} \frac{pdv}{v} \) are immediately determinable from the indicator diagram and \( k_v \) and \( k_{v0} \) are known from, e.g., Table XI, for the values of \( T \) corresponding to \( p_v \) and \( p_0 v_0 \), it is clear that equation (74') enables \( H - H_0 \) to be readily ascertained.

If in any specific case the expansion (or compression) curve can be approximated by an equation of the form \( p_v = a\left( 1 - \frac{T}{T_0} \right) \) (33), then in such cases we have by aid of equation (33)

\[
H - H_0 = \frac{a}{R} \left( 1 - \frac{T}{T_0} \right) \left( p_v - p_0 v_0 \right) - k_{v0} \left( k_v - k_{v0} \right). \tag{74'\prime}
\]
values over a number of successive small ranges of temperature, and drawing a series of curves within each range agreeably with the equation \( pV^n = \text{constant} \).

From equations (9), (12), (13), and (73) we obtain as the equation of entropy

\[
\phi - \phi_0 = n \log \frac{T}{T_0} + c' \log \frac{V}{V_0} - \Delta n \int_{T_0}^T \frac{e^{-\gamma}}{T} dT,
\]

where, putting \( \phi - \phi_0 = 0 \), we have for the isothermal equation

\[
c' \log \frac{V}{V_0} = \Delta n \int_{T_0}^T \frac{e^{-\gamma}}{T} dT - n \log \frac{T}{T_0}. \tag{76a}
\]

The impossibility of expressing the integral \( \int \frac{e^{-\gamma}}{T} dT \) in finite terms renders these two equations unsuitable for arithmetical computation.

§ (77) CLARK'S RESULTS. — Referring to these results of Clark, Callendar \(^1\) remarks: "Since the temperature of a mass of gas when exploded in a closed vessel or in the cylinder of a gas engine is far from uniform, and since the actual distribution of temperature is necessarily somewhat uncertain, it is evident that the variation of the specific heats of the constituents with temperature cannot be certainly deduced from a knowledge of the heats of combustion and the effective temperature, . . .

"It is possible, however, by explosion experiments to deduce values of the apparent or effective specific heats which, in so far as they approximate to the conditions existing in an actual gas engine, may be of greater practical utility than the true specific heats.

. . . The method of Dougald Clark in which the specific heat is directly determined from the work done on the charge after ignition,

\[\text{appears to be particularly appropriate for this purpose.}\]

It will be observed that Clark's results are somewhat higher than those of others; Callendar has stated (ibid.) that the values of the specific heats deduced from explosion experiments usually come out higher than those obtained by more direct methods, and considers that the errors incidental to both methods require further investigation.

§ (77').—According to the kinetic theory of gases, their internal energy is the sum of the translational, rotational, and internal-vibrational energies of their constituent molecules. Of these, the translational motion alone causes the gaseous pressure; the internal-vibrational produces radiation; while the rotational appears to have no external physical effect. Callendar \(^2\) points out also that theory indicates that the energies of molecular translation and rotation should vary directly as the product \( pt \), while the vibrational energy should vary with the temperature agreeably with a formula of the exponential type \( e^{(\beta_1 T_0 - 1)} \). This is symbolically expressed by writing

\[
\Pi = \text{internal energy} = \xi pt - \lambda e^{(\beta_1 T_0 - 1)},
\]

where \( \xi, \alpha, \beta, \lambda \) are constants.

The product \( pt \), though very nearly constant, appears to be expressible as a function of \( p \) and \( T \); thus Kelvin (Math. and Phys. Papers, vol. 1) found that for the usual permanent gases, including \( CO_2 \), an equation of the type \( pt = e^T - k(p/T) \) will resume the observed facts. Taking this, we have

\[
\Pi = e^T - k(p/T)^2 - \lambda e^{(\beta_1 T_0 - 1)}; \tag{77}
\]

whence

\[
\left( \frac{d\Pi}{dT} \right)_p = e^T - 2k(p/T)^2 + a_1 \frac{e^{(\beta_1 T_0 - 1)}}{T^2}. \tag{78}
\]

From these considerations it seems just possible that the extremes shown by which Clark's experimental results are resumed' by equation (73) may be somewhat nearer than a coincidence.

§ (78) VANALIERE'S EXPERIMENTS.-In an ideal perfect gas both \( k_p \) and \( k_v \) are constant, and the quantity \( R \) in the characteristic equation \( pv = RT \) . . . (12) being equal to \( k_v - k_p \) is also constant. But, as has already been pointed out, equation (12) is also true for fluids for which \( k_p \) and \( k_v \) are any functions of \( T \), provided only that \( k_v - k_p \) is constant; and such fluids will obviously obey Boyle's Law, since \( pv \) will still be constant when \( T \) is constant. Suppose, then, that \( k_v = \beta(T) \) and \( k_p = f(T) + R \); if heat \( dH \) be supplied to unit mass of such a fluid we shall have by equation (10) all heat-quantities being expressed in work-units:

\[
dH = pv dt + pd\theta \tag{13},
\]

If the changes be isothermal, \( dt = 0 \), and hence whatever \( f(T) \) may be, we must have

\[
dH = pd\theta \text{= external work} - \text{as in the ease of a perfect gas already considered. As by equa-}
\]

\(^1\) Gaseous Explosive Committee of British Association, 1st Report, 1903, p. 27.

\(^2\) ibid., p. 32.
tation (12) \( p = R/T/V \), equation (13) gives at once the equation of entropy

\[
dP = \frac{dU}{T} = \frac{R(TdV - dT)}{V} = \gamma dV - \frac{R}{V} dT = 0. \tag{76}
\]

Putting \( dP = 0 \) gives as the differential equation to the adiabatic,

\[
\frac{R}{T} dV + R \frac{dV}{V} = 0. \tag{77}
\]

§ (79) VALUES OF \( K_p \).—It is now fully established that \( k_a \) for gases is not constant but that it increases with the temperature (and probably changes slowly also with density), and the results of experiment are very commonly resumed by simple equations of the form

\[
k_a = a + bT. \tag{78}
\]

Thus Clerk has given the following as fairly resuming Mauard and Le Chatelier's experimental results:

<table>
<thead>
<tr>
<th>Gas</th>
<th>( k_a = a + bT )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nitrogen</td>
<td>(-171 + 0009216T)</td>
</tr>
<tr>
<td>Steam</td>
<td>(-316 + 000182T)</td>
</tr>
<tr>
<td>CO</td>
<td>(-1425 + 0006831T)</td>
</tr>
<tr>
<td>Oxygen</td>
<td>(-106 + 000185T)</td>
</tr>
</tbody>
</table>

in C./T.U. per lb., and \( T \) in \( ^\circ \) C. (abs.).

It may be pointed out here that in all cases where the efficiency of a cycle is expressible by equation (71), any increase in the value of \( k_a \) diminishes the efficiency, and vice versa. For doubling density by \( 
\rho \) and putting \( V/k_a \) for \( \gamma - 1 \), equation (71) becomes

\[
\eta = 1 - \frac{1}{\rho} R/k_a \tag{71a}
\]

and differentiating all across with respect to \( k_a \) gives

\[
\frac{d\eta}{dV} = \frac{R}{k_a} \left( \frac{1}{\rho} \right) \frac{dR}{dV} + \frac{R}{k_a} \left( \frac{1}{\rho} \right) \frac{dR}{dV}. \tag{71b}
\]

As \( R \), \( k_a \), and \( \rho \) are essentially positive, and \( \rho \) is always \( > 1 \), \( d\eta/dk_a \) is always negative, and thus \( d\eta \) and \( dV \) have opposite signs.

§ (80) ESTIMATION OF \( H - H_a \) FROM INDICATOR DIAGRAMS.—When \( k_a \) is expressed in the simple form as given in equation (78), we have for the increase in internal energy at constant volume corresponding to a change of temperature from \( T_a \) to \( T \)

\[
H - H_a = \alpha(T - T_a) + \beta(T^2 - T_a^2). \tag{79}
\]

From equations (13) and (79), when \( \alpha \) changes, all quantities being expressed in working-units,

\[
H - H_a = \alpha(T - T_a) + \beta(T^2 - T_a^2) + \int \frac{p}{\gamma} dV. \tag{79a}
\]

As \( pV = RT \) . . . (12) this may be written

\[
H - H_a = (pV - pV_a) \left( \frac{\alpha}{R} + \beta \frac{T}{R} \right) + \int \frac{p}{\gamma} dV. \tag{79b}
\]

and all the quantities on the right-hand side of this equation being immediately determinable from the indicator diagram, the value of \( H - H_a \) is known when using any working mixture for which \( \alpha \) and \( \beta \) and \( R \) have been previously ascertained.

Whenever the expansion or compression curve can be expressed in the form \( pV = \text{constant} \), equation (79b) by aid of equation (30) takes the simple form

\[
H - H_a = \left( \frac{\alpha}{R} + \beta \frac{T}{R} \right) \int \frac{p}{\gamma} dV. \tag{79c}
\]

Also, equation (76) becomes

\[
dP = \left( \frac{\alpha}{R} + \beta \frac{T}{R} \right) dV + R \frac{dV}{V} = 0. \tag{79d}
\]

the differential equation of entropy, giving on integration

\[
\phi - \phi_a = a \log \left( \frac{T}{T_a} \right) + \beta \left( T - T_a \right) + R \log \left( \frac{V}{V_a} \right), \tag{80}
\]

whence, putting \( \phi - \phi_a = 0 \), we have as the adiabatic equation in terms of \( V \) and \( T \),

\[
a \log \left( \frac{T}{T_a} \right) + \beta \left( T - T_a \right) + R \log \left( \frac{V}{V_a} \right) = 0. \tag{80a}
\]

which is also sometimes written in the form

\[
\left( \frac{T}{T_a} \right)^\frac{\alpha}{R} + \beta \left( T - T_a \right) = 1. \tag{80b}
\]

From the relation \( pV = RT \), equations (82) and (82') may also appear as

\[
a \log \left( \frac{p}{p_a} \right) + \beta \log \left( \frac{V}{V_a} \right) + \beta \left( T - T_a \right) = 0, \tag{80c}
\]

or

\[
\frac{p}{p_a} = \left( \frac{V}{V_a} \right)^\frac{\alpha}{R} \beta \frac{T}{T_a} \tag{80d}
\]

and

\[
\alpha \log \left( \frac{p}{p_a} \right) + \beta \log \left( \frac{V}{V_a} \right) + \beta \left( T - T_a \right) = 0. \tag{80e}
\]

On putting \( \beta = 0 \), equations (82), (83), and (84) reduce to equations (22), (20), and (21) respectively.

§ (81) Otto CYCLE WITH VARIABLE SPECIFIC HEAT.

H:AT.—It is of interest to compare the efficiency of the Otto cycle using a fluid of variable specific heat with that obtained on the usual simplifying assumption that \( k_a \) is constant, as in §§ (30) and (43) ; the data assumed are as in § (51), viz., \( V_a = 300 \) c. (lbs.), \( T_a = 600^\circ \) C. (abs.), \( T = 2000^\circ \) C. (abs.), and \( p_a = 14-7 \) lbs. per sq. in. (abs.) ; see Fig. 21.

Instead of air, the working fluid is now 1 cwt. ft. at \( 0^\circ \) C., and atmospheric pressure, of Clerk's gas-engine mixture as described in § (74), obeying the law

\[
14-7 p = 7-75 T. \tag{81a}
\]
The variation of $k_v$ with temperature is exhibited in Fig. 33, plotted from Table XL, and from this curve the following linear formulae are easily deduced for the value of $k_v$ over the four temperature ranges taken:

<table>
<thead>
<tr>
<th>Temperature Range in °C. (Abs.)</th>
<th>$k_v$ in Ft.-lbs./Cub. Ft.</th>
<th>$a + bT$</th>
</tr>
</thead>
<tbody>
<tr>
<td>300-500</td>
<td>16.8 + 0.01T</td>
<td></td>
</tr>
<tr>
<td>500-1000</td>

<tr>
<td>1500-2000</td>
<td>26.5 + 0.0003T</td>
<td></td>
</tr>
</tbody>
</table>

Then to obtain points on the adiabatic compression curve we have the relations

$$v = (300/273) \times 1 \times 1-0092 \text{ cub. ft.},$$

whence equation (82) becomes, using common logs,

$$16.8 \log \left( \frac{T}{300} \right) + 7.754 \log \left( \frac{v}{1-0092} \right)$$

$$+ 6.343 \times 0.1(T - 300) = 0.$$  

Assuming a series of values of $T$ between

200° C. and 600° C., this equation gives immediately the corresponding values of $v$; and $p$ is then found from $v$ by aid of equation (12). Proceeding in this way we get

$$T = 300 \quad 350 \quad 400 \quad 500 \quad 600$$

$$v = 1-0090 \quad 0.739 \quad 0.5913 \quad 0.4338 \quad 0.3169$$

$$p = 14.7 \quad 23.7 \quad 42.2 \quad 68.5 \quad 92.9$$

from which the compression curve can be plotted. The explosion pressure $P$ is obtained from $P/p = T/k_v$; thus substituting the values $P = 202 \times (2000/900) = 673.3$ lbs. per sq. in.

The adiabatic expansion curve may next be obtained by the same method as that adopted for the compression curve, taking $a = 20.5$ and $β = 0.6065$ from 200° C. to 1600° C., and $a = 23.2$, $β = 0.6097$ from 1600° C. to 1000° C.; this furnishes the following figures:

$$T = 2000 \quad 1600 \quad 1200 \quad 1000$$

$$v = 1.1900 \quad 1.918 \quad 3.156 \quad 4.413 \quad 5.806$$

$$p = 1-28 \quad 2.53 \quad 3.25 \quad 3.81 \quad 4.18$$

The $p\varepsilon$-diagram plotted from these results is shown in Fig. 30; it will be noted, by

The $p\varepsilon$-diagram plotted from these results is shown in Fig. 30; it will be noted, by comparison with the results obtained for the case in which $k_v$ is constant, working between the same limits of temperature, and with the same temperature of compression, the ratio of expansion variable specific heat in 0-87, at 5-47, when $k_v$ is constant; while the mean pressure with variable $k_v$, due to the change of compression ratio, is also greatly

Then to obtain points on the adiabatic compression curve we have the relations

$$v = (300/273) \times 1 \times 1-0092 \text{ cub. ft.},$$

whence equation (82) becomes, using common logs,

$$16.8 \log \left( \frac{T}{300} \right) + 7.754 \log \left( \frac{v}{1-0092} \right)$$

$$+ 6.343 \times 0.1(T - 300) = 0.$$  

Assuming a series of values of $T$ between

200° C. and 600° C., this equation gives immediately the corresponding values of $v$; and $p$ is then found from $v$ by aid of equation (12). Proceeding in this way we get

$$T = 300 \quad 350 \quad 400 \quad 500 \quad 600$$

$$v = 1-0090 \quad 0.739 \quad 0.5913 \quad 0.4338 \quad 0.3169$$

$$p = 14.7 \quad 23.7 \quad 42.2 \quad 68.5 \quad 92.9$$

from which the compression curve can be plotted. The explosion pressure $P$ is obtained from $P/p = T/k_v$; thus substituting the values $P = 202 \times (2000/900) = 673.3$ lbs. per sq. in.

The adiabatic expansion curve may next be obtained by the same method as that adopted for the compression curve, taking $a = 20.5$ and $β = 0.6065$ from 200° C. to 1600° C., and $a = 23.2$, $β = 0.6097$ from 1600° C. to 1000° C.; this furnishes the following figures:

$$T = 2000 \quad 1600 \quad 1200 \quad 1000$$

$$v = 1.1900 \quad 1.918 \quad 3.156 \quad 4.413 \quad 5.806$$

$$p = 1-28 \quad 2.53 \quad 3.25 \quad 3.81 \quad 4.18$$

The $p\varepsilon$-diagram plotted from these results is shown in Fig. 30; it will be noted, by

The $p\varepsilon$-diagram plotted from these results is shown in Fig. 30; it will be noted, by
ment of these areas, or by direct calculation of the quantities of heat received and rejected at constant volume from equation (70), the value of $T^*$ (at II) being taken from the $T-\phi$ diagram; both methods agree in giving 0-44 as the value of the efficiency.

With constant specific heat it has already been shown that for the Otto cycle the efficiency is $1 - (k_e/k_a) = 0-4$ (vide equation (70)) and § (45)) thus when $k_e$ is expressible in the form $\alpha + \beta T$ and $(k_e - k_a)$ is constant, efficiency is diminished.

§ (83) OTTO CYCLE IDEAL EFFICIENCY.—
Clark has calculated by a method of successive approximations values of the ideal efficiency of the Otto cycle when using the mixture of gases whose Apparent Specific Heat is as given in Table XI, and his results are given hereunder; corresponding values of efficiency with constant $k_e$ are given, calculated from equation (71). It will be observed that the efficiency with variable $k_e$ is always less than that with $k_e$ constant.

§ (84) EFFICIENCY; “AIR STANDARD”—It has already been pointed out (§ (37)) that $1/\rho$ denotes the value of the adiabatic compression ratio in the three ideal cycles of constant pressure, constant volume, and constant temperature, then the efficiency is, in each case, expressed by the same formula, viz.

Efficiency $= 1 - \left( \frac{1}{\rho} \right)^{\gamma - 1}$. (71)

If the working fluid be air assumed as possessing a constant value of $\gamma = 1-4$, this equation becomes

Efficiency $= 1 - \left( \frac{1}{\rho} \right)^{4}$. (71)

and in this form is termed the “Air Standard” of efficiency, and has been largely employed in the past as representing the theoretical maximum of performance for any given value of $\rho$.

It is clear, however, from the above discussion that when the specific heat is variable, and not constant, that equation (71) represents an unattainable ideal. Clark has pointed out that in the cases taken in Table XIII, the “air standard” values are roughly about 20 per cent too high. Much more information is, however, still required before even the apparent specific-heat values are accurately known for the various mixtures of gases and vapours employed in gas and oil engines. When these values become accurately assignable each engine can be separately investigated and the real efficiency of its working fluid determined. The proportion borne by the actual thermal efficiency as determined by tests to the real efficiency will then give a true measure of the degree of excellence of its performance, and indicate the exact margin remaining for improvement.

On the general question of the values of $k_e$ and $k_a$ for gases and gaseous mixtures reference may be made to the 1st and 2nd Reports (1908-9) of the Gas and Air Explosions Committee of the British Association. Clark (Proc. I.C.E., 1907), however, makes the useful suggestion that if $\gamma$ be taken at the constant value 1-285 for the expansion curve, and at 1-370 for the compression curve, then for the range of temperature met with in gas-engine practice no serious error is introduced.

3. O.

3. A. N.

ENGINES, SOME TYPICAL INTERNAL COMBUSTION

§ (1) The “Internal” Combustion engine is so called because the gaseous or vapourised fuel, mixed with air, is burned or exploded within the working cylinder itself, in contrast with earlier types of heat engine in which the working fluid, steam or air, is generated or heated by an external furnace. For the history of the development of the Internal Combustion engine reference may be made to Sir D. Clark’s work on The Gas, Petrol, and Oil Engine (Longmans, 1900).

The engineering thermodynamics of Internal Combustion engines are dealt with in the article “Engines, Thermodynamics of Internal Combustion”; in this article some account is given of typical actual engines.

§ (2) THE CYCLE.—All modern internal combustion engines work on either the four-stroke or two-stroke cycle, with combustion either at constant volume or at constant pressure, or at a combination of both these methods. Of these the constant volume (Otto) four-stroke cycle engines form by far the largest class. A very great deal of attention is, however, now being given to the improvement of the two-stroke cycle engine, which has long been established as
a reliable and economical prime mover in large stationary engine practice, and is now rapidly increasing in favour, in single- and two-cylindered designs, in the small quick-speed petrol types used in the propulsion of motor-launches and cycles on account of its great simplicity and relatively low production cost. Its extended adoption in motor vehicles in general is regarded as not unlikely in the near future.

The constant pressure class, typified by the Diesel engine, in both four-stroke and two-stroke designs, includes also the somewhat numerous so-called "semi-Diesel" engines, of which one is described and illustrated later. In these "semi-Diesel" oil engines the fuel admission is, in general, so regulated that combustion takes place partly at constant volume, and partly at (approximately) constant pressure.

§ (5) The Pilot—The fuels now successfully employed are also numerous and various. Among gaseous fuels are: Coal gas; pressure and suction producer gases (Dawson, Mond, National, Crossley, etc.); coke oven gas; blast furnace gas; natural gas (mainly in the U.S.; principally CH4); and water gas. Of liquid fuels may be mentioned petrol; naphtha, paraffin, or lamp oil; intermediate oils; gas oils; crude oils (filtered and freed from volatile constituents); residual oils; benzol; shale oils; coal tar oils; liguette oils; and alcohol; and mixtures of these, as, e.g., of petrol, benzol, alcohol, and kerosene. Solid fuels are not yet practicable, though, in the laboratory, Diesel engines have been made to run on coal dust, and engines of the Otto-cyclo motor-car type on naphthalene.

§ (4) The following have been selected for description and illustration as typical engines exemplifying present-day practice:

A. CONSTANT VOLUME TYPE

(a) As a four-stroke Stationary Horizontal Single-cylindered engine of medium power—the 100 Horse-power "National" gas engine.

(b) As a four-stroke Stationary Vertical Multi-cylindered engine of medium power—the Two-crank, 300 Horse-power, Tandem Four-cylindered engine of the National Gas Engine Co.

(c) As a four-stroke Stationary Horizontal Two-cylindered engine of large power—the Double-acting Tandem Single-crank 2500 Horse-power Nurnberg gas engine.

(d) As a two-stroke Stationary Horizontal Single-cylindered engine of small power—the early Clerk gas engine.

(e) As a two-stroke Stationary Horizontal Single-cylindered Double-acting engine of large power—the Körting gas engine.

(f) As a special two-stroke Stationary Horizontal Single-cylindered Single-acting engine of large power—the Oechslehausener gas engine.

(g) As a typical "Paraffin" engine—the Hornsby-Almeyd oil engine.

B. CONSTANT PRESSURE TYPE

(4) A description is given, with illustration, of a normal four-stroke Diesel engine, with some account of the two-stroke Diesel, and an illustrated description of a Ruston "semi-Diesel" engine. The large class of small, usually multi-cylindered, quick-revolution internal combustion engines as used for the propulsion of motor vehicles, launchers, aircraft, etc., form the subject of a separate section.

§ (5) (a) THE 100 H.P. HORIZONTAL "NATIONAL" GAS ENGINE. (i.) Description.—

A vertical longitudinal section of this single-cylindered engine is shown in Fig. 1. Within the "working barrel" or "cylinder liner" AA slides a cast-iron piston BB attached to the crank-shaft by the connecting rod CC. The piston fits the cylinder very accurately, but complete gas-tightness is ensured by six cast-iron spring rings DD. The piston is held by means of the lubricator EE and through the hole shown in the piston "skirt" oil is also enabled to reach the "small end" or "gudgeon bearing" of the connecting rod. At the left-hand end of the cylinder is the combustion chamber FF, within which are placed the inlet valve I and the exhaust valve K; holes above these valves, filled by easily removable plugs LL, permit them to be readily withdrawn for examination and repair or replacement.

The working barrel of the cylinder, the combustion chamber, and the valve casings are all well cooled by a water jacket WWW; it will be seen that the combustion chamber is a casting separate from that of the working barrel, and that the inlet valve casing is also a separate casting. By disconnecting these three castings all jacket water spaces are exposed, and can be thoroughly cleansed from deposit; as pointed out in the article "Engines, Thermodynamics of Internal Combustion" (§ (6)), adequate cylinder and combustion chamber cooling becomes a matter of increasing importance as the dimensions of gas engines become larger. The arrangement here adopted necessitates making a double joint; of these the inner is made with asbestos, and is screwed up hard so as to be tight under the explosion pressure; the outer joint, having only to maintain jacket water tightness, is made with yielding rubber. The valve-stem guides are also separate castings easily replaceable after wear; in the case of the exhaust valve it will be seen that the design permits close access of cooling water all round the stem; the exhaust valve seat is also so arranged as to be efficiently water-cooled.
The cylinder has a bore of 16 inches with a piston stroke of 22 inches; the piston and valves are not water-cooled. The working barrel, or cylinder liner, MM, is screwed up hard to the combustion chamber casing at the rear (left-hand) end, while at the front end an expansion joint is provided with the jacket casing PP; the working barrel becomes much hotter than the outer casing of the jacket, and it is very necessary to make provision in this way for the difference of expansion thus arising in order to prevent the creation of large internal straining actions with consequent risk of distortion or rupture of casings.

A light cast-iron oil trough RR fluted in the crank-jit prevents waste oil from saturating the engine foundations.

(ii) Method of Working.—To start the engine, the fly-wheel is pulled round by hand until the piston has definitely commenced its working stroke; an explosive mixture of coal gas and air is then pumped by hand, through a small auxiliary valve, into the combustion chamber; failing coal gas a small quantity of petrol is used. The explosive mixture thus introduced is then fired by a spark at the ignition plug S obtained by operating the (low-tension) magneto by hand. A working stroke of the piston immediately occurs, and considerable momentum is imparted to the fly-wheel; the subsequent order of operations is as follows:

1. During the return stroke of the piston the exhaust valve K is lifted and the burnt gases are discharged through the exhaust pipe, and silencing apparatus, into the atmosphere; (2) during the second out-stroke the inlet valve I is open and a fresh charge of gas and air is drawn into the cylinder; (3) the second in-stroke then follows, compressing this fresh charge into the combustion chamber H; (4) at the commencement of the next out-stroke the mixture is ignited by a spark at the ignition plug S, explosion occurs, and the piston is driven forward. This cycle is then repeated continuously so long as the engine runs.

It will be seen, therefore, that the engine works upon the Otto, or four-stroke, cycle, of suction, compression, working, and exhaust strokes, and that the piston accordingly receives one working impulse in every two revolutions of the crank-shaft; the momentum of the very massive fly-wheel T preserves the necessary degree of uniformity of rotation.

The engine is governed by a variable admission device operated by a governor of centrifugal type by which the masse of the charge and also the supply of coal gas are reduced as the load on the engine is diminished. Below quarter load the governor acts by cutting out ignition.

(iii) Details of Working.—The ratio of compression, 1/p, is about 10:1, whence by equation (71) of the "Engines, Thermodynamics of Internal Combustion," article, the "air standard" efficiency is \(1 - (1/p)^{0.4} = 0.404\); with this value of 1/p, which corresponds to a compression pressure of about 140 lbs. per sq. in. (abs.), pre-ignition is avoided without the necessity of injecting a spray of water into the cylinder at full load running. If \(p\) denotes the mean effective pressure during the working stroke, in lbs. per sq. in., as ascertained from an indicator diagram, and if

\[d = \text{Diameter of piston, in inches},\]
\[s = \text{Stroke of piston, in inches},\]
\[n = \text{Number of revolutions per minute of crank-shaft},\]

then the work done by the engine is expressed
by $\pi/4 \times d^2 \times p \times 2 \times 12 \times \pi s/2$ foot-lbs per minute, and the indicated horse-power (I.H.P.) is

$$\frac{1520000}{d}$$

The Brake Horse-power (B.H.P.) is less than the I.H.P. by the power necessary to overcome the frictional and fluid resistances of the engine itself; the ratio B.H.P./I.H.P. is termed the mechanical efficiency of the engine, and is usually denoted by the symbol $\eta$; hence, as $\eta = \text{B.H.P.}/\text{I.H.P.}$, we have from equation (1)

$$\text{B.H.P.} = 0.92, d^{2} \times p \times 10^{-8}$$  (1)

The product $np$ is termed the "brake mean effective pressure," and is largely used in calculations of the performance of small fast-running internal-combustion engines of the point motor type with which it is impossible to obtain reliable indicator diagrams under ordinary circumstances. The total distance, $s$ feet, covered by the piston in one minute is termed the "piston speed," and is evidently equal to $2\pi s/12$; thus

$$\text{Piston speed} = \frac{\pi s}{6}$$  (3)

(iv) Performance.—The performance of this 100 h.p. National gas engine has been ascertained by numerous tests in practice, and has been found to be as follows:

<table>
<thead>
<tr>
<th>Fuel used</th>
<th>Maximum B.H.P.</th>
<th>Maximum I.H.P.</th>
<th>Mechanical Efficiency $\eta$</th>
</tr>
</thead>
<tbody>
<tr>

while the piston speed corresponding to 210 r.p.m. is 770 feet per minute. Horizontal single-cylindrical "National" gas engines of this type are built up to a maximum of 185 brake horse-power; for higher powers multiple cylinders are used, in both horizontal and vertical arrangements; one of the latter is next described.

§ (6) (b) THE 300 H.P. VERTICAL "NATIONAL" GAS ENGINE. (1) Description.—A transverse section of this four-cylindered two-crank tandem gas engine is shown in Fig. 2.

The engine comprises two pairs, each consisting of two cylinders A and B placed one above the other, each pair being connected by a connecting rod C with a crank D; the upper pistons are each 18 inches in diameter and the lower each 17 inches, with a stroke of 18 inches; and the engine runs normally at 300 revolutions per minute, so that the piston speed (equation (3)) is 900 feet per minute.

The upper and lower piston of each pair are connected by a cast-iron sleeve, or distance piece, 41 inches in diameter, through which passes a long nickel steel bolt by means of which the three pieces are tightly held together; the pistons are not water-cooled but are cast with an internal cooling web 132 which assists in the conduction of heat from the piston crown—normally one of the hottest parts of an internal-combustion engine. Gas-tightness is ensured by the five cast-iron spring rings shown; near the bottom of the skirt of the lower piston is placed a sixth, or "scraper," ring, to prevent the passage past the piston of oil from the crank chamber.

The lower portion of the upper cylinder contains only air, which is alternately compressed and expanded during the running of the engine, and by its "cushioning" action contributes greatly to softness of running by assisting to reverse the motion of the pistons when at the bottom of their stroke; the cranks are also balanced to further aids smoothness in running.

Each cylinder liner with its water jacket casing is a separate casing, but there is a gap at the lower end of each between liner and casing which is fitted with a water-tight packing ring so arranged as to permit any relative movement due to difference of expansion; the lower portions of the cylinder liners are not water-jacketed.

The inlet valves I, I' and exhaust valves K, K' open into a common port, and are placed one above the other, the inlets being on top. Both inlet and exhaust valves are of cast-iron, as are also the canned seats in which they rest; the seats are, however, separate rings capable of easy removal and replacement after wear. The inlet valves carry on their stems gas valves M, M', which have no seats, but slide within a well-fitting cylindrical housing; the gas and air supply passages are formed by the partitioned casing N, N'. The gas valves M, M' open later and close earlier than the charge inlet valves I, I'; this practice is common to all large gas engines and is adopted to avoid risk of pre-ignition of fresh charge by any residual smouldering or highly heated exhaust gas remaining over from the
When the inlet valve opens at the end of the exhaust stroke, the combustion chamber contains hot burnt gases from the previous explosion; the first flush of pure air cools this, and the subsequent supply of mixed gas and air can then safely enter. Towards the end of the suction stroke the gas valve closes, and the final suction is from the lower air chamber $N'$ only; thus when the charge inlet valve closes, $N'$ is filled with pure air in readiness for the commencement of the next suction stroke.

A centrifugal shaft governor regulates the supply of mixture to the engine by the "quantity" method, in which the composition of the charge remains sensibly constant, while its mass is varied to suit the load. Forced lubrication is used for all reciprocating parts.
cating and rotating parts, the oil being supplied by engine-driven valvesless pumps at a pressure of 20 lbs. per sq. in.; after the oil returns to the crank casing and drains into a " sump," where it is filtered before passing into the oil pumps by which it is again delivered to the bearings. The lower cylinders are lubricated by the oil which comes from the cross-head or "gudgeon" bearings, while the upper cylinders and top metal-packed Joint of the piston rod where it passes between the two cylinders are supplied by a sight-feed lubricator fed by a small pump operated by the engine. Starting is effected by means of compressed air. Ignition is by high-tension magnets, with two "sparking plugs" PP in each cylinder.

The arrangement of the valve-driving shaft, which is gear-driven from the crank-shaft so as to run at half-speed in a four-stroke cycle engine, is clearly indicated in the figure; the cams and rollers by which the valves are operated are of case-hardened steel.

(ii) Performance.—On test, one of those engines developed 404 indicated horse-power, and 368 brake horse-power at 290 revolutions per minute; the power was absorbed by a Heenan and Froud hydraulic brake. These engines are gas-driven, and the known value 0.896, we have also for the mean effective pressure, \( p = \frac{57 \times 896}{1000} = 0.036 \text{ in.} \), per sq. in.

Tandem single-acting vertical engines of this type are made from 185 to 1000 horse-power; the 1000 H.P. engine has eight cylinders (four pairs) operating four cranks. The cylinders of each pair are 22 inches and 23 inches in diameter respectively; the stroke is 24 inches, and the normal revolution speed is 200 per minute, the corresponding piston speed being 800 feet per minute.

§ (7) Relation of Weight to Power.—In all engines the weight per unit of power developed increases with increase in dimensions, and this is one of the reasons in favour of the adoption in many cases of the multi-cylindered design. The following Table, compiled from actual engines, brings out this point clearly; the rated B.H.P. is, given, using blast-furnace gas as fuel; and the engine weights per B.H.P. are given exclusive of weight of fly-wheel.

In large horizontal tandem double-acting gas engines the inclusion of the fly-wheel weight adds from 50 to 60 lbs. to the weight per B.H.P. The fly-wheel alone of a 1000 B.H.P. engine of this type commonly weighs about 35 tons.

</table>

* The relative piston speed is twice as great in these, the "Dechallume" engines; see § (11) infra.
† Koehler Engines; see § (10) infra.

Results give the high value 0.896 for the mechanical efficiency; to determine the value of \( \eta \), equation (2) must obviously be modified for this case and written

\[
\text{B.H.P.} = \frac{2 \times 892 \times 10^{-6} \times \text{amp.} \times (1.0)^2 + D_2^2 \times d^2}{4}
\]

\( D_2 \) and \( d \) being the respective piston diameters, and \( d \) that of the piston rod; all in inches.

For a B.H.P. of 300, this equation gives \( \eta = 0.037 \) lbs. per sq. in. As in this case \( \eta \) has

§ (8) (e) The Tandem Horizontal Numerburg Engine. (i) Description.—The design selected as typifying a modern big four-stroke gas engine is that of the 2500 horse-power, two-cylindrical, tandem, double-acting, horizontal, single-crank engine of the Maschinenfabrik Augsburg Nurnberg, A.G.—usually styled, for brevity, the Nurnburg Co., of which a longitudinal section is given in Fig. 3.

The two cylinders \( A, A' \) are placed in line, with their pistons mounted on a common piston rod \( B B' \) to one end of which the connecting
rod C is attached; the whole power of the engine is transmitted by this connecting rod to the single crank D; the crank-shaft carries a massive fly-wheel, by the momentum of which the necessary degree of uniformity of revolution is maintained. This engine is double-acting, that is, each cylinder is closed at both ends, and both sides of each piston receive power impulses. As a single-acting, single-cylindered, four-stroke engine receives one power impulse in every four strokes of its piston, it is clear that in this case as the power impulses are four times as frequent there is a power impulse at every stroke; the engine thus runs with very little variation in its revolution-speed.

(ii.) Cooling Arrangements.—British practice so far has generally favoured the single-acting unstepped piston, on the score of simplicity in details, and this practice has limited piston diameters to a maximum of about 26 inches. With a big double-acting engine, water- or oil-cooling of the pistons, and even also of the exhaust valves, becomes necessary. In this case the pistons only are water-cooled, the water being introduced through the hollow piston rod as shown in the illustration.

The cylinders and cylinder covers are, of course, also water-jacketed; the ample water-spaces provided will be noted in the section, and it will be seen that care has been taken to bring the water close up to the valve seatings: it is found that a water pressure of about 15 lbs. per sq. in. above atmospheric suffices to maintain an efficient circulation through the jackets. For the piston rod and pistons, however, it is found necessary—on account of their rapid heating motion—to provide a water pressure of from 45 to 65 lbs. per sq. in. Water from the mains is frequently available at this pressure, but when this is not the case a pump is provided, driven by the engine, which delivers the cooling water at the necessary pressure.

The water-cooling system is well arranged throughout; each cylinder is fitted with an open water-tank into which all water drain-pipes discharge in full view of the attendant, and each discharge is provided with a thermometer and a regulating valve so that the temperature of each part can be adjusted independently as desired. To avoid the necessity of shutting each outlet valve when the engine is stopped, a main stop valve is fitted in the supply pipe, and this valve is closed only when the engine is not running.

(iii.) Lubrication.—The lubrication of the external bearings is effected from a large oil-bank situated above the engine from which the oil is conducted through pipes of ample diameter fitted with regulating valves, to the various points. Surplus oil is drained away and collects in a sump in the engine house, by the engine. Rolling levers and eccentrics are grease-lubricated. For the forced lubrication of the cylinders, piston rod stuffing-boxes, and exhaust valve guides, special oil pumps are provided, and the supply to each point can be independently
ENGINES, SOME TYPICAL INTERNAL COMBUSTION

regulated. The piston rod stuffing-boxes are protected with a series of rings of similar section each in three parts, made alternately of cast-iron and white metal; these are pressed against the surface of the rod by symmetrically disposed circumferential helical springs; lubricating oil under pressure is delivered into the middle of each stuffing-box. Wear is found to be very small, and is confined to the packing rings, which are easily adjusted or renewed.

In illustration of the efficiency of the cooling and oiling arrangements provided in these large engines, it may be stated that a Nuremberg engine of 2000 horse-power working with blast-furnace gas ran day and night for a period of nineteen months. The engine was actually running for 98.5 per cent of the possible working hours, and the 1.7 per cent of stoppages were due to works repairs

the piston rod in the stuffing-boxes; this not only saves wear but also considerably reduces the internal friction of the engine. Gas-tightness of the pistons is insured by six self-tightening packing rings.

(v.) Governors.—The engine is governed on the “quantity” method, by which the composition remains practically constant, while the mass admitted is proportioned to the power output required. Should the quality of the gaseous fuel vary, the ratio of gas to air can be adjusted by hand while the engine is running.

Two ignition plugs are fitted in each cylinder, actuated by small electromagnets forming part of the plugs.

(v.) Performance.—Table II gives the results of tests on a 1200 brake-horse-power Nuremberg engine using blast-furnace gas having a heat value per cubic foot of about

and in no way in any defect of the engine. At the end of this long period of service the engine was reported as in excellent working order, and continued in operation.

(v.) Piston Rods.—An important detail of construction is that whereby the heavy water-filled pistons are prevented by their weight from causing “avalling” or undue wear of the lower portions of the cylinders and stuffing-boxes. The long hollow thick-walled tubes of which the piston rod is built up are turned with a slight upward camber so that the rod, when heated with the pistons, and supported by the three crossheads E, F, G, is exactly straight; arrangements are also provided in addition whereby each piston can be readily adjusted independently to the exact centre of its own cylinder. The whole weight of the pistons and rod is thus borne by the three external crosshead-plates, and the pistons accordingly “float” in the cylinders as does

50 C.T.H.U.; the pistons were 33-46 inches in diameter (piston rod about 8” inches dia.), with a stroke of 43-3 inches.

With reference to this Table it may be observed that the revolutions per minute, n, are directly counted, and that the value of the mean effective pressure, p, in lbs. per sq. in. is ascertained from indicator diagrams taken from both cylinders, the average value being tabulated. The indicated horse-power may next be calculated, equation (I) being modified to suit this type of engine by writing

\[ I.H.P. = d \times 102 \times 10^{-6} \times n \times (p^2 - d^2), \]  

D and d being the diameters in inches of the pistons and piston rod respectively.

The brake horse-power is directly measured, and thence the value of the mechanical efficiency is calculated. It will be observed that the frictional and fluid resistances of the engine itself absorb about
Engines, Some Typical Internal Combustion

260 horse-power when running at 106 revolutions per minute. The brake mean effective pressure, $\mu$, is now known and tabulated. The total consumption of gas per hour in cubic feet is directly measured, and dividing the figures obtained by the I.H.P. and B.H.P. the gas consumption in cubic feet per hour per I.H.P. and B.H.P. respectively. The heat value of the gas per cubic feet is determined by calorimetric tests, and hence the heat supplied in C.T.H.U. per hour per I.H.P. and per B.H.P. is immediately ascertainable.

Finally, as one horse-power hour corresponds to $33,000 \times \frac{1}{60} = 1414$ C.T.H.U. per hour converted into mechanical work, the absolute thermal efficiency of the engine is determined by taking the ratio of 1414 to the heat supplied to the engine in C.T.H.U. per horse-power per hour.

Thus, at full load, this engine showed an absolute brake thermal efficiency of 28.5; that is to say, 28.5 per cent of the whole heat supplied to the engine appeared as useful external work. In one hour the working volume swept through by the pistons is $\pi/4 (D^2 - d^2) L = 1282$ cubic feet; and at full load the heat evolved in C.T.H.U. per hour is $1427 \times 1429$, whence in this case the evolution of heat in C.T.H.U. per cubic feet of working stroke swept out by the pistons has the value 22.6 (see the article, "Engines, Thermodynamics of Internal Combustion," § (60)).

§ (9) (a) Two-stroke Engines: The Early Clerc Engine. (l) Description.—The low frequency of but one working stroke in four of the Otto cycle has always been regarded as a serious disadvantage, and very numerous attempts have for long been made to increase the impulse frequency without sacrificing the valuable practical advantages of simply and effectively charging, exploding, expanding, and exhausting—combined with high thermal efficiency—which are possessed by the four-stroke engine; no solution has even yet been found which fully satisfies the commercial conditions for both large and small engines.

The first explosion compression two-stroke or "impulse every revolution" engine was invented and built by Clerc in 1876, and the Clerc two-stroke cycle engine, with improvements in detail suggested by experience, is still, particularly for large engines, that which most successfully satisfies everyday requirements.

A section of the Clerc two-stroke engine is shown in Fig. 4; an engine to this design was shown at the Paris Exhibition of 1881. It was of the horizontal, single-cylinder, single-acting type, and comprised a motor, or working, cylinder A containing exhaust ports E, E', near its outer end, and a displacer cylinder B; within these cylinders respectively work pistons C and D, suitably connected to a common crank-shaft. The crank-pin driving the displacer piston D was about $90^\circ$ in advance of that operated by the motor piston C.

(ii) Method of Working.—The order of operations is as follows: Near the end of the working (out) stroke the motor piston C overruns the exhaust ports E, E', and the burnt gases immediately escape thence into the atmosphere. Simultaneously the displacer piston D, being in advance of the motor piston, has passed the end of its out-stroke and has commenced to return; during its out-stroke it has drawn into the cylinder B an explosive mixture of gas and air through the sliding valve H and pipe W. The commencing return of the piston D causes the mixture in B to become slightly compressed before the complete exhaust of A, but not sufficiently to cause any material resistance; in the delivery pipe connecting the two cylinders is an automatic inlet valve; as soon as the pressure from B slightly exceeds that in A, this valve rises and the fresh mixture then enters the combustion chamber G. The return of the motor piston C then causes the automatic inlet valve to close, and subsequently compresses the entrapped fresh charge into the chamber G; this is then fired at the instant of maximum compression, explosion occurs, and the working stroke follows. Thus every out-stroke of the piston C is a working stroke, and the impulses are therefore one per revolution of the crank-shaft, and are accordingly twice as frequent as in the "Otto" four-stroke cycle.
ENGINES, SOME TYPICAL INTERNAL COMBUSTION

(iii) Difficulties.—In the ideal two-stroke motor the operations of charging and exhausting would be performed at least as effectively as in the four-stroke engine, and hence, the working impulses being as frequent, a two-stroke engine of given bore and stroke should develop at least twice as much power as the equal four-stroke, with the same thermal efficiency. In practice, however, there are certain fundamental difficulties of the two-stroke cycle which have so far prevented the realization of this ideal. Thus, in the Otto cycle the inlet valve usually opens slightly before the end of the in-stroke of the working piston and remains open not only throughout the whole suction out-stroke, but also for a short period after its completion; the suction, or "charging" period accordingly continues during about 220° of the crank-throw revolution. In the two-stroke engine, however, the fresh charge has to be introduced into the motor cylinder while the crank-throw turns through only about 80°. Hence the duration of the charging operation in the Otto cycle is nearly three times as long as in the Clerk cycle. Though this disadvantage is reduced by providing specially large inlet valves and exhaust port areas, it remains still that the two-stroke engine is not in general capable of being charged so effectively as the four-stroke, and also that more power is absorbed in the charging operation.

A second point is that in the Otto cycle the exhaust valve is open during about 220° of the crank-throw revolution, and hence the burnt gases have considerable time in which to escape, and are moreover assisted in their exit by the return of the motor piston during the whole exhaust stroke, so that there remains finally only the combustion chamber filled with residual exhaust at, or even slightly below, atmospheric pressure. In the Clerk cycle engine, on the other hand, exhaust has to be accomplished during the very short interval occupied by the motor piston in passing over the last part of its out-stroke and first part of the subsequent in-stroke, so that not only in the combustion chamber, but also in the working cylinder there remains some but exhaust gas. The effect of this is to reduce the quantity of fresh charge that can be introduced into the motor cylinder, i.e. to diminish the "volumetric efficiency" of the engine, with consequent diminution in the output of power. Further, the commencement of the introduction of the fresh charge while the exhaust ports are still uncovered causes a loss of unburnt mixture by "short-circuiting" direct through the exhaust ports into the atmosphere. Waste of fuel from this cause is frequently considerable in the very small petrol-type a-stroke motor. In large two-stroke engines, however, this cause of loss is almost completely avoided, (a) by providing a combination chamber of somewhat elongated conical form as shown at G (Fig. 4), and introducing the fresh charge at the commencement of the same, and (b) by sending first into the motor cylinder a preliminary charge of air only to help in the scavenging and cooling of the residual exhaust gases, and following this up by the introduction of a corresponding rich mixture of gas and air; this practice, initiated by Clerk in 1891, is still followed in all large gas engines. The doubled frequency of working impulses in the two-stroke engine causes necessarily an increase in the mean heat-flow from the cylinder per second, and hence in the design of this type of engine special attention has to be given to the details of the cooling arrangements.

(v) Performance.—These early Clerk two-stroke engines were constructed in sizes of from 2 to 12 nominal horse-power, and the following test results obtained in 1894 from a series of these engines are still of much interest; the fuel used was Glasgow coal gas, and the figures given are from the usual trials which were carried out on all engines before leaving the manufacturers' works, and thus fairly indicate the performance of the engines in ordinary service.

The mixture delivered by the dilator contained 1 volume of coal gas to 8 volumes of air; on passing through the inlet and mixing with the residual exhaust gases in the motor cylinder it becomes further diluted. The increase of temperature acquired by contact with the exhaust and with the cylinder walls expands the entering fresh gas a temperature of at least 100° C., being commonly attained before compression commences. The expansion of the entering fresh gases thus caused expels more of the exhaust products through the ports than would correspond to the volume swept through by the motor piston between the closing of the exhaust ports and complete in-stroke. Through "turbulence" mixing occurs to a considerable extent and the net result is the formation of a mixture explosive in every part of it, and of an average composition of 1 volume of coal gas to 9 volumes of other gases; thus the proportion of exhaust gases present is but small; that there is any at all arises from the necessity of preventing any appreciable loss of fresh mixture through the exhaust ports. The mixture employed was a comparatively rich one.

(v) Efficiency.—In these engines the value of the compression ratio, 1/p, was 3½; whence the "Air Standard" efficiency is 1 - (1/3·5) 0·5 = 0·36. Regarding this as the highest conceivable efficiency, the degrees of excellence of the engines given in the table are to be estimated...

The Clerk two-stroke cycle is very successfully utilised in the special design of large horizontal gas engine made by Messrs. Körling of Hanover, and the Do La Vergne Co. of New York; a typical section is shown in Fig. 5. The engine is of the single-cylindered double-acting type, and working on the two-stroke cycle, thus furnishes two impulses per revolution of the crank-shaft as in an ordinary steam engine. It comprises a closed, water-jacketed, cast-iron cylinder AA provided with a ring of exhaust ports BB at the middle of its length, and containing a very long piston CC which overruns the ring of exhaust ports in its reciprocations, opening these ports to the one end of the cylinder and the other alternately. The piston is attached to a piston rod which passes through a stuffing box in the cylinder cover and is connected to an external crosshead as in ordinary steam-engine practice; hence the

\(\text{T}_F(\text{c})\) Tum Körling Enotra. (i.) Descriptions.—The Clerk two-stroke cycle is very
power is transmitted to the crank-shaft by a connecting rod as usual. The external crosshead not only keeps the "gudgeon" bearing or "small end" boring of the connecting rod cool, but also relieves the piston of the lateral thrust due to connecting-rod obliquity, and thus much reduces cylinder and piston wear. Large gas engine cylinders are usually lubricated, and using gas free from dust, show but little wear, a 409 B.H.P. cylinder after one year's working, for example, showing an average wear of only 0.13 of an inch. The cylinder is closed by deep cast-steel well water-jacketed covers or heads, in which are housed the cages containing the mixture inlet valves D, normally held up against their seats by helical springs, and opened during the necessary intervals by a simple arrangement of rods and levers operated by a single eccentric on the crank-shaft.

In these large engines, instead of the single "mixture pump" or "displacer" of the Clerk engine, separate double-acting pumps are provided, in which supplies air only and the other gas only. The displacer crank is placed about 100° in advance of the main crank, as in the Clerk engine, and thus the air pump piston has travelled a short way on its discharge stroke when the inlet valve opens. The gas pump, however, is so arranged that gas is not delivered until somewhat later. Thus a considerable volume of air only flows into the cylinder at first, displacing and cooling the hot exhaust gases, so that when the fresh unburnt gas enters later it mingles with the relatively cool air in the cylinder, and thus risk of pre-ignition is minimized. It is very important in large gas engines to arrange that no explosive mixture should be formed in cylinders or passages; in the Körting engine the gas meets and mixes with the air just above the intake valve. In small gas engines the gas and air may be mixed in the pump or "displacer," a back-fire into the pump being of little importance; in a large engine, however, in similar circumstances, the result of a back-fire might easily prove a serious matter.

(ii.) Method of Working.—The charge having entered the cylinder—first air only and then mixed gas and air—the exhaust products having been thoroughly displaced, the working piston has closed the ring of exhaust ports by a crank movement of 40° to 45° from the dead centre. Compression then occurs, followed by ignition and subsequent expansion. The air pump valves are so arranged as to deliver a full charge of air at every stroke whether the engine be light or loaded, but the gas delivered by the gas pump varies in amount as determined by the governor. Ignition is electric, and occurs at two points at each end of the cylinder and means are provided by can be regulated by hand while the engine is running; on gases, as e.g. blast furnace gas, ignition is earlier than producer gas, and a mixture of gases is liable to variation in quality. This adjustable ignition arrangement is very useful. Running at light loads, the mixture of gas and air admitted after the preliminary discharge of air only being of practically constant composition, a readily ignitable charge always exists at the ignition plugs, and thus regular firing is ensured at light loads.

(iii.) Performance.—Körting engines having an aggregate of fully a quarter of a million horse-power have been built, and they compete strongly against the four-stroke type; they are built in sizes of from about 1,000 B.H.P. with a 22½ inch cylinder and 3½ inches stroke, running at 110 revolutions per minute, to 2,000 horse-power from a single cylinder of 43 inches diameter, the stroke being 5½ inches, and speed up to 30 revolutions per minute. The following results were obtained on test with a 600 B.H.P. Körting engine in 1891 (Mango):

| Diameter of double-acting air pump | 31-4 in. stroke, 43-5 in. |
| Diameter of double-acting gas pump | 27-0 in. stroke, 42-5 in. |
| Fuel | producer gas from anthracite |
| R.H.P. developed in working cylinder | 815 |
| R.H.P. of engine | 673 |
| Fluid resistance | 611.8 |
| Ratio of pump resistance in total | 0.104 |
| Power—Piston speed | 235 ft. per minute. |
| Mean effective pressure, p, on power piston | 52-6 lbs. per sq. in. |

Boiler works at 220 lbs. per sq. ft. of surface. Steam at 80 lbs. per sq. ft. of surface, and is supplied at a pressure of 75 lbs. per sq. ft. No water is used in the engine. Steam tempering is not required.

Estimating the mechanical efficiency as the value of the ratio R.H.P./Total I.H.P. gives 79.078, which is rather low, and is due to the somewhat high pumping resistances which in this particular engine amounted in 10-26 per cent. of the total I.H.P.; in later designs the pumping resistances have been much reduced and the mechanical efficiency correspondingly increased. For weight per B.H.P. of this type of engine see Table II. (supra).
The eburneit gas immediately escapes through the ports C and are assisted in their exit by the charge of fresh air under slight pressure which enters through the ports G. This fresh air mingles with, and is forced through the exhaust ports when the gas is subsequently admitted through the ports F. The mutual approach of the two Pistons reduces the parts and the entrapped mixture is next compressed between them; at the end of the (compression) stroke, the mixture is fired electrically as usual, and the expansion (working) stroke then follows.

The doubleacting pump must act on one side as an air pump and on the other as a gas pump; gas and air are separately pumped into the separate reservoirs K and L respectively, wherein they are stored at a pressure of 5 to 6 lbs. per sq. in. above atmosphere.

It will be seen that with this arrangement no gas and air mixture exists anywhere but actually within the working cylinder. To further diminish loss of unused gas through the exhaust the maximum quantity of gas and air delivered into the cylinder is only about 0.7 of the cylinder volume. (Governing is effected, as in the Kötting engine, by reducing the gas charge at light loads.

The crankshaft has three throws; to the middle throw piston B is linked by the usual connecting rod, while the two side throws are linked by side connecting rods M, M' to crossheads O, O', which are coupled up by rods P, P' to the bridge-piece Q carried on the piston rod R of piston B'; thus the crankshaft is subjected to a practically simple torque, and the cylinder is not required—as in all other engine designs—to supply the reaction to the motions on the working piston; as a consequence the engine frame and cylinder can be made lighter than usual.

In the design illustrated the gas and air pump is shown driven directly by the piston rod R, but in later designs the engine dimensions are much reduced and weight diminished by placing the pump at the side of the working cylinder and driving it from a disc crank-pin on the end of the crank-shaft. The cylinder also has been much shortened by the ingenious device of fitting spring rings in each of its ends, which rings bear upon the piston surfaces; in this way the pistons can be arranged to protrude from the cylinder ends by a considerable amount at out-strokes, much as in the case of an ordinary plunger pump. To prevent "smoking" of the pistons both are rigidly attached by short piston rods to sliding crossheads guided both vertically and horizontally.

(ii.) Forking.—The two large pistons alternately issuing from and reentering into the working cylinder set up pulsations in the atmosphere of the engine-house, and these may cause troublesome rhythmic vibrations of windows, partitions, etc.; this action is greatly reduced in cases where two engines are installed in the same engine-house with crankshafts so arranged as to differ in phase by 180°.

![Diagram](image-url)

The two moving pistons cause the rates of compression and expansion of the working gases to be taken as rapid as usual, which is thermodynamically advantageous.

(iii.) Performance.—Tests by Professor Moyer in 1903 on a 600 h.p. Baurig-Ochsenbauer engine furnished the following results:

and the average consumption on these tests was 16.8 cubic feet per total I.H.P. hour.

The absolute thermal efficiencies realised were:

- Absolute indicated thermal efficiency: 286-290-292-294
- Absolute brake thermal efficiency: 290-293-298-306

The mechanical efficiency, taken as the value of the ratio B.H.P./Total I.H.P., varied from 0.67 to 0.75, a somewhat low result; the joint-pumping resistances ranged from about 9 per cent at full load to 13 per cent at the lowest test load—calculated relatively to the total I.H.P.

The consumption of lubricating oil in the working cylinder was as the average rate of 1.18 lb. per hour. At full load 5 gallons of water were used per total I.H.P. hour; the cooling water temperature on entering was 22°C, and on leaving 42°C; hence 44×20 = 880 C.Th.U. of heat were off by the cooling water per I.H.P. hour; so that, at full load, the heat expenditure amount was roughly:

- Heat Expenditure per Total I.H.P. Hour, C.Th.U., Per cent.

| Converted into mechanical work | 1440 | 30 |
| Carried off in cooling water   | 880  | 24 |
| Carried off in exhaust gas and general heat losses | 1535 | 37 |
| Total                         | 2057 | 100 |

(iv.) Indicator Diagram.—In obtaining indi-

cator diagrams from an engine in its normal 
to compare the recorded diagram, that the 
angle through which the fuel is delivered 
the piston through the stroke. In the case of the 
Orchard-Horners engine a special procedure 
the two pistons move exactly alike, in the explosion position the 
middle throw of the crankshaft, which is 
driven by the front piston—iat its inner 
dead center while the two side throws are 
driven by the back piston—are at their center 
dead centers. When the double working stroke 
commences, due to commutating and elasticity, 
the front piston travels more rapidly than the 
back piston, and this continues until it nearly 
half stroke, thereafter the front piston moves 
more slowly than the back. Thus Fig. 7 shows 
the bottom heavy line the diagram obtained 
from an engine with reference to the back 
piston; when the back piston has moved 
through 0.7 strokes the pressure will be given by 80. 
As at the same instant the front piston has 
described nearly its stroke and hence reached some point, as 7, the diagram is continued to meet a horizontal through 8 in 12. It is evident that B is a point on the diagram corresponding to the front piston. In this way the front piston diagrams can be constructed, as shown by the dotted full line; midway between B and 8 is the converted diagram of which the mean effective pressure is deduced. In some cases the two M.R.P. is as much as 10 per cent greater than that deduced from the single diagram as given by the indicator.

§ (12) DAY'S MEASURING. (b) Description. — 
The ingenuity two-stroke cycle valveless engine 
vented by Deppe in 1891 may be briefly referred 
to here as it is largely used at the present day 
in very small sizes, e.g. in the (petrol) 
engines of motor bicycles, handcars, etc. The
The ascent of the piston causes a partial vacuum in the crank-chamber, and when near the top of its stroke its lower edge uncovers the port A, thus allowing an incoming of carbureted air. The subsequent descent of the piston first cleans A and then compresses the charge in the crank-chamber to 3 or 4 lbs. per sq. in. above atmospheric pressure. When near the bottom of its stroke, the upper edge of the piston first uncovers the exhaust port B, and then the inlet port C; the lip D on the piston deflects the entering stream upwards so as to minimise loss of fresh charge by "short-circuiting" through the exhaust port. The piston next rises, cutting off the ports C and B, and compressing the fresh charge into the combustion head.

Experiments on an engine of this type by the late Professor W. Watson and Mr. Penning in 1910 showed that the proportion of each fresh charge which escaped unburnt through the exhaust port was considerable at low speeds, but diminished as the speed increased, as shown hereunder:

<table>
<thead>
<tr>
<th>At Revolutions</th>

</tr>
<tr>
<td>1800</td>
<td>6</td>
</tr>
</tbody>
</table>

The mean effective pressure was much higher at low than at high speeds, ranging from about 62 lb. per sq. in. at 600 r.p.m. to 44 lb. per sq. in. at 1800 r.p.m. The volumetric efficiency was only about 40 per cent, and varied but little with speed, the greater loss of fresh charge through the exhaust port at low speeds approximately counter-balancing the larger volume of charge then entering the cylinder.
Owing to the relatively large proportion of burnt exhaust gases in the charge when fired, the “mixture” supplied to this type of engine needs carefully adjusting within somewhat narrow limits in order to obtain regular

or “lump oil”), gas oils, intermediate oils, crude oils, residual oils, and even tar oils.

The following table gives some figures obtained from tests of samples of the more usual oil fuels:

Figures for petrol are given to enable a comparison to be made with the heavier oils; it will be observed that for the heavy American and Russian petroleum oils the average (lower) calorific value in c\(\text{Thi.} / \text{lb.} \) varies but little from a mean of 81,500.

§ (14) (g) Description.—Numerous devices are employed in heavy oil engines to vaporize the charge of oil forming the explosive mixture with air. The type here selected for description and illustration is that in which a combined vaporiser and explosion chamber is formed as a prolongation of the cylinder combustion chamber; of this type the best known example is the Thomas-Akroyd engine, of which a longitudinal section is shown in Fig. 9.

The engine is of the usual horizontal, single-acting, single- (or double-) cylindered, four-stroke type, but is provided at the combustion chamber end with a partly or wholly immersed smaller vessel, termed the "vaporiser" or "hot-bulb," which is constantly in free communication with the cylinder through a relatively narrow neck or "choke." Inside the cylinder is also provided with an air inlet and an exhaust valve of the usual types, both non-operated, which are not shown in the figure.

The oil tank is formed in the engine head-plate; a centrifugal governor regulates the engine speed by opening a by-pass when the speed increases, thus permitting a portion of
the oil delivered by the oil pump to pass back into the oil tank.

(ii.) Method of Working.—To start the engine the unjacketed portion of the vaporiser is first heated by a blow-pump for about 10 minutes; the fly-wheel is next turned by hand and the piston performs its suction stroke, drawing, through the inlet valve, a charge of air only into the cylinder. This air enters the cylinder direct, without passing through the vaporiser. Simultaneously a charge of oil is sprayed into the "hot-bulb" by the oil pump shown, and this at once vaporises. On the return stroke of the piston the air is compressed, and a portion passes through the neck B and mixes with the vaporised oil. The mixture is at with resulting deposition of carbon, which in time chokes up the vaporiser. The temperature is regulated by admitting more or less water to the jacket C which surrounds the neck and part of the vaporiser itself. In many hot-bulb engines, however, pre-ignition at heavy loads is avoided by allowing a few drops of water to enter the chamber during the later stages of compression. On the other hand, the vaporiser may become too cool when the engine is run at light load, and in this case the lamp must be used.

(iii.) Performance.—A test of a 25 horse-power Horseby-Atwood oil engine made by Professor Robinson in 1898 gave results as follow: Piston diameter, 14.5 in.; stroke, 17 in.; fuel, "Russian." At full load the engine ran at 202.6 revs. per minute and gave 29.7-I. B.H.P., with a mechanical efficiency of about 84.5. The compression pressure was only 75 lbs./sq. in. (abs.); explosion pressure, 183 lbs./sq. in.

At full load the whole device is admirably simple and has proved very successful, and a great number of internal combustion engines, both of four-stroke and two-stroke type, are now made on the "hot-bulb principle." After running for a few minutes it is found that the blow-lamp may be removed, the hot-bulb temperature being thereafter sustained by the heat communicated to it from the successive explosions; the ignition then becomes completely automatic. If the vaporiser be allowed to become too hot pre-ignition occurs, and the oil may also be "cracked,"

first too rich to ignite, but the engine is so adjusted that just as compression is completed the correct explosive mixture is reached in the hot-bulb; the heat of the walls then causes explosion and the piston moves outward and performs its working stroke; this is followed by the exhaust in-stroke, and the cycle then recurs. The whole device is admirably simple and has proved very successful, and a great number of internal combustion engines, both of four-stroke and two-stroke type, are now made on the "hot-bulb principle."

After running for a few minutes it is found that the blow-lamp may be removed, the hot-bulb temperature being thereafter sustained by the heat communicated to it from the successive explosions; the ignition then becomes completely automatic. If the vaporiser be allowed to become too hot pre-ignition occurs, and the oil may also be "cracked,"

(iii.) Performance.—A test of a 25 horse-power Horseby-Atwood oil engine made by Professor Robinson in 1898 gave results as follow: Piston diameter, 14.5 in.; stroke, 17 in.; fuel, "Russian." At full load the engine ran at 202.6 revs. per minute and gave 29.7-I. B.H.P., with a mechanical efficiency of about 84.5. The compression pressure was only 75 lbs./sq. in. (abs.); explosion pressure, 183 lbs./sq. in.

The oil per B.H.P. hour was 0.74 lb., corresponding to an absolute brake thermal efficiency of 188. The heat compression pressure for use with any given oil is found by experience; thus "Russian" was found to permit a higher compression, and to give 15 per cent to 20 per cent more power than "Royal Daylight." Compression may be varied by fitting different-sized vaporisers, and in engines of over about 50 B.H.P. by fitting distance-pieces to the crank-pin end of the connecting rod in addition. These engines run best on kerosene, and particularly with the standardised Russian oil of 855 sp. gr. and 30° C. flash-point by Abel close test; they have, however, also been run on crude, gas, and residual oils.

Later tests have furnished still better results; thus in 1908 Professor Robinson
obtained from a 32 B.H.P. Hornby-Okroyd engine using Russian oil. (Cal. value in this case 10,250 C.T.R.U. per lb.) A consumption of only 0.413 lb. per B.H.P. hour, corresponding to an absolute brake thermal efficiency of 29.6.

Single-cylindered engines are constructed up to 185 B.H.P., and with two cylinders to 370 B.H.P.

§ (15) (h) The "Constant-Pressure" Cycle Diesel Engine. (i) Description.—The leading characteristics of the Diesel engine are: (1) the compression of air only up to the maximum pressure attained in the cylinder, usually from 450 to 500 lbs. per sq. in.; and (2) the regulated admission of the fuel, usually a heavy mineral oil—blown into the combustion chamber by a blast of very high pressure air—in a state of extremely fine spray, during the first part of the working stroke, so that it burns at approximately constant pressure, the ignition occurring automatically from the high temperature developed in the adiabatically compressed air. The cycle has been considered from the thermodynamic standpoint in the article on "Engines. Thermodynamics of Internal Combustion."

A section through a usual type of four-stroke Diesel engine is shown in Fig. 10. It will be seen that the engine is of the inverted vertical single-cylinder type, comprising a long and heavy piston A working within a well water-jacketed cylinder B, and driving the crank-shaft C through the usual type of connecting rod D. In the deep water-cooled detachable cylinder head E are situated the air inlet and exhaust valves (not shown in the diagram), which are of the usual "poppet" or "induction" type, normally held up to their seat by springs and opened inversely by exhaust or overhead instead of through the agency of roller-ended rocking levers as indicated. The shaft H is of course driven at half the speed of the crank-shaft. The fuel injection valve K is also located in the cylinder head, and in recent designs is generally placed in the centre; it is a fundamental difficulty in all internal combustion engines wherein the fuel is sprayed into the combustion chamber at or near the instant of maximum compression to secure a uniform mixture giving rapid and complete combustion, and some of the earlier Diesel designs failed largely from this cause alone. By placing the fuel injection valve in the centre of the cover, and so forming its orifice—and often the upper surface of the piston.
(ii.) Method of Working.—The engine is started as follows: By means of a hand lever the crank-shaft is rocked round until the crank-pin is just over the top centre; next a starting lever is operated by which a starting cam is brought into working position. The fuel blast reservoir valve and starting reservoir valve being next opened, air from the latter at a pressure of 700 to 800 lbs. per sq. in. enters the cylinder through a small starting valve situated in the cover, and the engine immediately moves off. After a few revolutions under the compressed air from the reservoir the starting lever is moved back, and the engine at once takes up its normal working cycle and continues to run. The full revolution rate is attained at once, but the normal power output is not reached until the cylinder is well warmed up.

In the case of a new engine the air reservoir for starting is sent out fully charged; thereafter its pressure is maintained by a small pump driven by the engine itself.

The charge of fuel is also blown into the cylinder through the fuel injection valve by a blast of air from this reservoir.

The fuel injection valve comprises a needle valve held down on its seat by a spring and lifted by a cam-operated lever. A fuel force-pump delivers the charge of oil fuel into a narrow annular space surrounding the needle which is also in constant communication with the air-blast reservoir during the running of the engine. Hence immediately the needle valve is raised the charge of oil is blown with great velocity into the combustion chamber through an expanding nozzle in the form of a uniformly diffused cloud of mist which instantaneously inflames in the adiabatically compressed air where temperature is at this instant from 500-650° C. The fuel is caused to enter the combustion chamber just before the completion of the compression strokes, and at full load the injection is continued during the first 20° to 30° of crank-shaft revolution, the mixture burning at approximately constant pressure during admission. Engine speed is controlled by a governor actuating a by-pass valve in the fuel pump supply whereby a variable proportion of the pumped oil is returned into the suction pipe as the engine load is varied.

The fuel injection needle valve must be regularly cleaned at intervals of about a fortnight; a sticky needle valve may cause pre-ignition through leakage of fuel oil during the compression strokes; such a defective valve, moreover, allows the very high pressure blast air to enter the cylinder in abnormal quantities, and this also may cause rupture of the cylinder through excessive pressure caused by its subsequent further compression by the rising piston. Provision is sometimes made against excessive pressure by fitting relief valves in the cylinder head.

The high-compression and air-blast pressures employed necessitate workmanship of the highest quality in the construction of the Diesel engine, and the necessity of providing against occasional abnormal pressures in the cylinder renders this type of engine somewhat heavy in relation to power output. The high compression also necessitates the fitting of very heavy fly-wheels in four-cylinder four-stroke engines in order to attain the requisite uniformly in rotation of the crank-shaft. For hand Diesel engines up to 200 H.P. the weights per H.P. (including fly-wheels) are, usually, as follows (compare Table I.):

(iii.) Fuels.—Experiments have been conducted with a great variety of fuels, including petrol, kerosene (lamp oil), gas oil, crude Russian, American, and German mineral oils, Astakh, shale oils, Castor oils, lubrication oils, palm and nut oils, castor oil, lard oil, alcohol, coal gas, producer gas, and coal dust. The greatest success has been attained with the kerosene and heavier petroleum oils, and it is on these, not particularly on the heavy dark-brown crude Texas fuel oil of specific gravity about 0.925, flash point about 85° C., and (lower) calorific value about 10,180 C.P.U. per lb.—as largely used for living steam boilers—that most Diesel engines in Great Britain are run. Dr. Allner, in a paper read before the German Gas Association in 1911, stated that the tar produced in large quantities in the coal-gas and coke-oven industries can be used successfully as a fuel for Diesel engines, provided a small quantity of a readily ignitable "pilot" fuel, as Texas oil, be injected either just before, or simultaneously with, the admission of the tar to the combustion chamber; the combustion of the pilot fuel starts that of the heavier fuel. Using gas oil as the pilot fuel, Dr. Allner affirms that crude tar may be used in Diesel engines.

In general, however, it is held to be a desideratum that the fuel employed should be free from tar, sulphur, and acid impurities. Coal dust, injected with a proportion of "lean gas," has been used—under experimental conditions only—as a fuel, and furnished indicator diagrams of normal type; but the difficulties of utilizing any solid substance as a fuel under ordinary conditions of working have yet to be overcome.

(iv.) Performance.—The economy of fuel with the four-stroke Diesel engine is very
Marked: a trial of a two-cylinder, 160 horse-power, four-stroke Diesel engine by Mr. Ada Clarke in 1905 furnished the following results:

Piston diameter, 15½ in.; stroke, 23½ in.
Fuel—Texas oil, 0-920 sp. gr.; calorific value, 16,720 C.P./lb. per lb. (higher value).

The outlet temperature of the cooling water, at full opening of the exhaust ports; the scavenging is not quite so good, but the engine is of greater simplicity in construction. As in all Diesel engines the fuel is not admitted until nearly the end of compression, any short-circuiting of air through the exhaust ports during its admission is immaterial.

* The R.H.P. was taken as total L.H.P. = 30-6.
† The mechanical efficiency was taken as R.H.P./total L.H.P.

Load, was 67° C. In the "No load" trial only one cylinder was producing power, the other pumping idle.

In May 1906 Mr. A. J. Pfeiffer stated before the Inst. of Electrical Engineers that there was then in service a four-cylinder, inverted-vertical, single-acting four-stroke Diesel engine giving 800 R.H.P. as 150 revs., per minute, and that this was about the largest that will run satisfactorily without water or oil-cooling the pistons and exhaust valves.

§ (16) (b) Two-stroke Diesel Engines.

(i) Description.—Marine Diesel engines are usually of the two-stroke type, single-acting, which possess advantages over the four-stroke of reduced weight and space, lower production cost, and greater simplicity in reversing. There are two principal types of two-stroke, single-acting Diesel engines, in both of which the piston overruns a ring of exhaust ports when near the bottom of its stroke—as in the Clark engine. In the one type—which is rather the more efficient—air inlet valves are provided in the cylinder head which are opened just after the exhaust ports are overrun, and effect a very complete scavenging action, leaving the cylinder filled with nearly pure air which is compressed by the piston during its return stroke as usual. In the other type, which has been developed largely by Messrs. Sulzer Bros., of Winterthur, the air inlet valves are disposed with, and inlet ports provided in the lower parts of the cylinder which are overrun by the piston shortly after the

A section through the cylinder of the 1915 design of "cold starting" engine is given.
In Fig. 11; the engine is of the horizontal, single-cylinder, single-acting, four-stroke type, and is built in sizes ranging from 20 to 170 horse-power.

On the intake stroke the piston draws in air only through the valve A, subsequently compressing this into the small explosion chamber B to a pressure of about 430 lbs. per sq. in., which is regarded as giving a sufficiently high temperature to ensure the ignition of any fuel oil. Just before compression is completed the charge of oil is injected directly into the explosion chamber through an "atomiser," whenupon it immediately ignites, and the working stroke then follows:

![Diagram](https://via.placeholder.com/150)

A normal fall-load indicator diagram is shown in Fig. 11a. Very perfect "atomisation" of the fuel is essential to high engine efficiency; the Ransom atomiser comprises a spring-closed needle valve and a number of small oil ducts converging to a central orifice. A small fuel four-pump operated by a quick-acting or "screw" cam compels the charge of oil delivered by it to lift the spring-closed needle valve; the charge is by this means caused to enter the explosion chamber in the form of an exceedingly fine spray or "mist"; the lift of the needle valve is of the order of two or three-hundredths of an inch only.

(ii) Method of Working.—By means of air started at a pressure of 200-300 lbs. per sq. in., a reservoir the engine is readily started, and after one or two revolutions picks up its working cycle; starting is thus effected from cold, and the engine may be run on any of the usual grades of fuel oil. When tar oils are employed it is necessary to use about 5 per cent of a more readily ignitable or "pilot" fuel to initiate combustion; this is introduced by a special atomiser fitted with a small needle valve inside a tubular, main fuel needle valve, served by a pilot oil pump. The spring-loaded plunger of this pilot pump is operated by fluid pressure from the main fuel pump in such manner as to absolutely ensure the injection into the cylinder of the pilot igniting charge immediately before that of the main charge. Test results show that, using a fuel of 0.92 sp. gr. and calorific value of about 10,000 C.T. units per lb. (lower value), the consumption per H.P. hour ranges from 0.48 lb. in the 20 horse-power engine, down to 0.10 lb. in the 170 horse-power size. This corresponds to an absolute brake mean effective pressure of 0.29 to 0.35, which compares favorably with ordinary Diesel practice.

§ 18 "Semi-Diesel" Engines.—The great economy of fuel consumption of the Diesel engine has caused many attempts to be made to produce designs in which, without much sacrifice of mean effective pressure and economy, production cost and weight are saved without having recourse to the high-compression pressure used in the Diesel engine, and further, by dispensing altogether with the costly and complicated high-pressure air blower which has so often proved a source of trouble and even danger.

As such designs have been evolved from a study of the performance of Diesel engines, they have come to be styled "semi-Diesel,"
though, as they employ a hot-bulb to ensure ignition of the sprayed charge of oil, they
would be more justly described as "Alroyd" engines.

(ii) The G.L. Engine. A good example of
this class is the "G.L." engine of Messrs.
Brown, Rand, Proctor & Co., of which a section
through the combustion chamber end of the
cylinder is shown in Fig. 12; the engine is
of the horizontal, single-acting, four-stroke
type.

Through the inlet valve A, air alone is
drawn during the suction stroke, and this is
next compressed into the combustion chamber
and hot-bulb B. Nearly at the instant of
maximum compression the charge of oil
fuel is injected into this hot-bulb by a
force-feed pump and atomizer as in the case
of the "cold starting" engine described in § (17).
The mixture is automatically ignited by the
hot-bulb as in the Thorndyke-Alroyd
engine, § (14), and after performing the
working stroke the burnt gases are discharged
through the exhaust valve E. The compres-
sion pressure employed is only about 275 lbs.
per sq. in., and mean effective pressures as
high as 80 lbs. per sq. in. are attained at
full load. These engines are built in single-
cylindered type up to 80 H.P., running at
100 revolutions per minute, and in two-
cylindered designs up to 130 H.P., at 300
revolutions per minute. As fuel, crude
petroleum, the ordinary fuel oils, and even
residual or "refuse" oils are used. A load of
a 50 H.P. engine in 1910 showed a
consumption of crude beans-oil of only
0.45 lb. per H.P. hour, corresponding to
an absolute brake thermal efficiency of
384.

Starting is accomplished by compressing the
air; the time occupied in starting three cold, owing
to the necessity of heating the hot-bulb by a blow
lamp, is 10 to 15 minutes. After a
short period of running the
blow-lamp is removed, and the hot-bulb returned to
then maintained by heat
derived from the successive explosions; the insulation is then
automatically, in the Thorndyke
Alroyd engine. To prevent
pre-ignition "lurce," from
occurring, a water dip is
used at three-quarters full
load and above; the water
spraying valve is indicated in
Fig. 12. After prolonged
running at light loads the
bulb may become too cold,
and recourse must then be
to the heating lamp in
order to maintain its tem-
perature. In this class of
engine the combustion of the fuel is
in general, partly at constant volume and partly
at constant pressure.

Entropy. If in a reversible change a sub-
stance receives or loses a quantity of heat Q at an absolute temperature T, the
substance is said to gain or lose an amount of
entropy given by Q/T. See also "Thermo-
dynamics." For Entropy of Fluids see
§ (33); Entropy of Ideal Gases, § (35);

Flash-point Determination

§ (1) Introduction.—The "flash-point" of a substance may be defined as that temperature at which it begins to evolve vapour in such quantity that, on the application of a flame, a momentary "flash" occurs, due to the ignition of the vapour. This temperature is not a definite physical property of the material, but varies with a number of subsidiary factors, such as the rate of heating, the amount of ventilation, the size of the applied flame, and so forth, and is thus dependent on the apparatus used and the conditions under which the determination is made.

Notwithstanding the empirical nature of this "constant" for an inflammable substance, it serves to classify such materials into varying degrees of danger with regard to fire risk, and from this point of view the determination of flash-point has been the subject of legislation and of official regulations.

A short consideration of the phenomena occurring when a sample of oil is slowly heated will serve to distinguish flash-point, burning-point, and ignition-point. If the oil is placed in a small metal basin or crucible and slowly heated, vapour is evolved at a rate depending upon the nature of the oil and its temperature. If a small test flame be applied periodically just above the surface of the oil, no result will be apparent so long as the temperature is well below the value known as the "flash-point" of the oil, but as this is approached the test flame will enlarge when in the neighbourhood of the surface of the oil, and at a temperature a few degrees higher this enlargement becomes more apparent and a flame rapidly travels over the surface of the oil and immediately dies away. This transient ignition of the vapour is termed the "flash," and the lowest temperature at which it is manifest is known as the "flash-point" of the oil. If the heating of the oil and the periodic application of the test flame be continued flashing will also continue, and it will be noticed that the duration of the flash becomes longer as the temperature is raised, until a point is reached when the vapour burns continuously instead of merely flicking; the lowest temperature at which this occurs is known as the "burning-point" of the oil. In general the heat generated by the combustion will rapidly raise the temperature and the combustion will become more violent, and will be maintained without the application of any external source of heating.

If now the experiment is repeated without the application of a test flame, there will be no apparent result until a temperature higher than the burning-point is reached, when the oil will spontaneously take fire and will continue to burn. The lowest temperature at which this takes place is known as the "ignition-point."

The above phenomena are dependent on the accumulation of sufficient vapour in the atmosphere above the oil to form a combustible mixture, and this will be largely influenced by any circulation which is taking place in the surrounding air. If the air is in motion, even to a small extent, some of the vapour will be carried away, and it will be necessary to raise the oil to a higher temperature to ensure the same concentration of vapour as would be obtained in perfectly still air. In consequence it is not easy to obtain consistent values for the flash-point, burning-point, and ignition-point, by the heating of the oil in an open cup as above described, and other types of apparatus have been designed to reduce the difficulty of making reasonably accurate determinations. In most forms of this apparatus the oil cup is provided with a cover having suitable apertures for the introduction of the test flame and for ventilation purposes. For distinction the two types of test are usually referred to as the "open test" and the "closed test" respectively.

The first apparatus of the "coloured test" type was introduced by Sir Frederick Abel in 1870, and was subsequently known as the Abel Flash-point Apparatus. A large number of tests were made to connect the results obtained by the use of this apparatus with those given by the open test then in use. It was found that the mean value of the difference between these results was 27° F. for an oil which flashed at 100° F. on the open test.

Later, in 1880, a modification of this instrument was made by Pensky, who applied a clockwork device to the oil cup so as to
perform the opening and closing of the shutter and introduction of the test flame. This apparatus is referred to as the Abel-Pensky Flash-point Apparatus. The provision of this mechanism is probably advantageous from the point of view of ease of operation, but, as will be seen later, it does not tend to any increased accuracy of determination of the flash-point.

The two apparatus above referred to were designed with special reference to the measurement of flash-points over the approximate range 60°-110° F. in connexion with the legislation relating to the sale, storage, and transport of illuminating oils; later, however, a demand arose for the determination of the flash-point of oils for lubricating and other purposes, leading to the evolution of such types of apparatus as the Gray and Pensky-Martens flash-point apparatus, which may be employed up to much higher temperatures. The essential difference between these and the earlier forms of apparatus intended for the lower range only is the provision of mirrors in the oil cups.

§ (2) Abel Flash-point Apparatus.-The official specification for the Abel flash-point apparatus will be found in the schedule to the Petroleum Act of 1879 (42 & 43 Vict. c. 47); full details as to the construction and use of the apparatus are also to be found in the several text-books relating to oil and oil testing. The principal dimensions are shown in Fig. 1.

An investigation was carried out at the National Physical Laboratory to ascertain the differences existing between the Abel and other types of flash-point apparatus.  

An important consideration that arises in the determination of the flash-point is the limit of accuracy attainable. The legal specification directs that the test flame should be applied to the oil every 1° F., and consequently the accuracy of any single determination is limited to 1° F. Departure from the specified conditions gives a different value for the resulting flash-point, as will be seen later.

Difficulties, however, arise in the interpretation of a set of results for any one sample of oil, since even when the greatest care is taken individual readings may differ by 1° or 2° F. Furthermore, changes in the barometric pressure produce variations in the resulting flash-point, and Sir Frederick Abel investigated this matter and found that the flash-point was raised by 10° F. for an increase of 1 in. in the barometric reading. Hence it is usual to correct all flash-points to a standard barometric reading of 30 in. Corrections for errors of the thermometer, if any, must also be taken into account; the most satisfactory way, therefore, of dealing with a set of observations is to obtain the mean result and apply the necessary corrections for pressure and for the thermometer. The true flash-point is then taken as the next higher whole number of degrees, since the flash-point of a substance as defined in the official regulations cannot be other than a whole number of degrees.

Before intercomparisons between the several types of flash-point apparatus could be carried out it was found necessary to investigate the conditions of use of the Abel apparatus more fully than appeared to have been done previously. Among the points to which attention was given were:

(a) Frequency of application of the test flame.
(b) Variations in the time of opening of the slide.
(c) Variations in the temperature of the water bath.
(d) Variations in the depth of the thermometer bulb below the surface of the oil.
(e) Size of the test flame.

The results of these experiments led to the following conclusions:

(a) Increasing the frequency of application of the test flame raises the flash-point; for example, if the test flame is applied every 1/2 degree the resulting flash-points are a degree higher, while if applied every 1/6 degree the flash-point is raised by over 3 degrees; conversely, a lower flash-point is obtained if the test flame is applied at intervals greater than 1° F.
(b) Contrary to the general opinion, the effect of increasing or decreasing the time for which the slide is open does not affect the results except for extreme changes. Thus the provision of an automatic mechanism to secure constancy in this condition is not essential. It is interesting to note in this connexion that a number of the Abel-Pensky automatic covers were investigated and it was found that their times of opening differed to a considerable extent. This might well be expected, as it is improbable that the strength of the spring would remain constant under the conditions of use.
(c) A change in the temperature of the water bath produces a corresponding change in the flash-point, the general effect being that the flash-point is lowered by 1° F. for each 13° F. rise in the temperature of the water bath above the normal temperature 130° F.

(d) and (e). The depth of immersion of the thermometer bulb below the surface of the oil and the size of the test flame were seen to play very important parts in flash-point determinations, and the question will be considered later.

§ (3) THE Abel-Pensky APPARATUS.—The apparatus adopted in 1880 by the German Government as the official standard design of instrument for flash-point determinations was based upon the Abel apparatus, but modifications were introduced by Pensky, who substituted an automatic device for opening and closing the ventilation holes and applying the test flame in place of the simple slide in the English Abel apparatus. In addition, the dimensions were slightly altered and were expressed in metric units instead of inches, as in the Petroleum Act of 1879. Fig. 2 indicates the important dimensions of the Abel-Pensky apparatus in accordance with the German schedule. Very complete details are published in the official specification and will not be further dealt with here.

The Abel-Pensky apparatus was also adopted by the British Colonies and India under the Indian Petroleum Act of 1880, the German type of apparatus being used although the dimensions of the Abel apparatus were retained. Two modifications have been made to the Colonial type of apparatus for special purposes; these provide for a small additional thermometer and a stirrer in the oil cup for use when obtaining the flash-point of inflammable substances such as rubber solution, metal polishes, etc., which may fall within the scope of petroleum legislation. In both these types of apparatus the effects of variations in the methods of procedure are the same as are described for the Abel apparatus.

§ (4) THE GENERAL THEORY OF Flash-Point Determination.—The general theory of flash-point determination depends on the hypothesis that flashing takes place when the space above the oil contains a definite percentage of oil vapour mixed with air. This condition will be reached for a definite temperature of the oil surface from which evaporation is taking place, and it is generally assumed that it is this temperature which is given by the thermometer and is the temperature taken as the flash-point. The rate of evaporation, however, depends upon the temperature of the surface of the oil, and investigation showed that this temperature differed appreciably from the thermometer reading throughout the course of a determination. Furthermore, the temperature at different points throughout the oil varied by several degrees at any one moment. The temperature distribution depended in part on the form and dimensions of the apparatus and on the relative amounts of heat reaching the oil from different sources. The method of investigation employed was to ascertain these temperature differences by means of differential thermocouples of very fine wire introduced in such a way as to avoid interference with the usual conditions of test. The main source of heat through which the rise of temperature of the oil is derived is of course the water bath surrounding the oil cups through the intermediary of the air space; but it was found that the temperature at the surface of the oil and that of the vapour were materially influenced by the heating derived from the test flame itself. The importance of the size of the test flame is therefore obvious, and as the result of a special series of experiments it was found that an increase of 2° F. in the flash-point was obtained when the size of the oil-burning test flame in an Abel apparatus was decreased to about half the normal diameter. Similar results were found for the gas test flames as in general use. The explanation of this difference is that with the smaller test flame the oil surface does not receive so much heat indirectly, and consequently the temperature of the bulk of the oil has to be mixed to produce the same surface temperature; thus the flash-point is apparently higher. For exact work it may be remarked that the ivory head on the cover of the apparatus is inadequate as a gauge for the adjustment of the size of the test flame. It is therefore preferable to employ a gas jet to which the supply of gas is controlled by a gas meter. In the experimental work to which reference is being made the gas rate adopted was 0.10 m. ft. per hour.

Investigation of the three types of apparatus, namely, the Abel, and the Colonial and the...
German types of Abel-Pensky apparatus, showed that the temperature distribution in each varied, so that for any definite reading of the thermometer the temperature of the surface of the oil was different in each of the three apparatus. It was further found that the temperature of the surface of the oil at the moment when flashing took place was the same in each of the three apparatus although the thermometer reading varied; the difference in flash-point recorded in the three types of apparatus is therefore completely explained by the consideration of the temperature distribution in the oil cups.

The general results of the investigation showed that the Colonial type of Abel-Pensky apparatus gave a flash-point 1°F. higher than the original form of Abel apparatus, while the German type of Abel-Pensky gave results approximately 4°F. higher; further, those differences are sensibly constant over the range 70°-100°F. Incidentally there is a systematic difference amounting to about 0.5°F. (taking the mean values for a large series of observations) between the results of the same type but fitted with oil and gas test flames respectively. As might be expected from the previous remarks, the gas test flame gives the lower flash-point, the flame supplying more heat to the surface of the oil, when adjusted to the specified size.

Further light is thrown on the mechanism of flash-point determination by the results of a series of tests carried out at the National Physical Laboratory at a later date.1 The tests in question were carried out on a number of fuel oils, using the Gray and Pensky-MacInnes apparatus, and also a modified form of apparatus on a flash-point 1°F. higher than the usual scale, which dealt with about 50 gallons of oil instead of the usual quantity. The latter apparatus was designed with a view to ascertaining whether a large quantity of oil would flash at a temperature appreciably lower than the value obtained in the normal types of apparatus. The conditions were varied over a wide range in order to study the effect of different methods of ignition and the importance of ventilation of the vapour space above the oil. Dealing with the latter point, it was clearly seen that combination of the vapour occurred prior to an actual flash being obtained; this is shown by the enlargement of the applied test flame at temperatures below the flash-point. If the space above the oil is not adequately ventilated it becomes charged with the products of combustion, which may lead to the extinction of the test flame or give an apparently high result. On the other hand, forced ventilation of the surface by the passage of a current of air apparently raised the flash-point, as in this case the oil vapour is swept away before ignition can occur. Consequently the oil has to be raised to a higher temperature in order to evolve vapour fast enough to maintain an inflammable mixture.

A variation of this point was also investigated. In this instance the oil was maintained at a constant temperature and the vapour was allowed to collect for periods of varying length; the test flame being applied after definite intervals had elapsed. Between such applications of the test flame the space above the oil was completely cleared of accumulated vapour by blowing a current of air through the space. The result of such tests was to show that the higher the temperature of the oil the shorter the interval that was necessary for the vapour to accumulate before the flash could be produced. At the lowest temperature at which it was possible to obtain any ignition of the oil vapour a comparatively long period (from 5 to 10 min.) was required before sufficient vapour had accumulated, and in these instances the flash, when it did occur, was violently of explosive nature. With regard to the effect of different methods of ignition, it was found that the most satisfactory results were obtained with a moderately-sized gas flame. Electric sparks or hot wires generally necessitated a higher temperature of the oil before flashing took place, and with the higher temperatures a violent, in some cases almost explosive, flash was obtained. Throughout these tests the oil was stirred continuously at such a rate that the temperature throughout the bulk of the oil was fairly uniform, but not so vigorously as to break the surface or to produce splashing.

Under these conditions it was found that the temperature in the vapour space immediately above the oil surface was sensibly the same as that indicated by the thermometer immersed in the oil; in other words, the question of temperature distribution met with in the Abel and allied apparatus does not arise here.

The ultimate deduction from these tests was that the Gray and Pensky-MacInnes apparatus indicate within a few degrees the lowest temperature at which it is possible for a flash to be obtained over this very wide range of conditions; and furthermore the Abel and Abel-Pensky types of apparatus could with advantage be modified by the introduction of a stirrer in the oil vessel and possibly in the vapour space above the oil. A small change in the indications of these apparatus would no doubt result, but the determination of flash-point would become an operation involving considerably less care and would not depend on any marked extent upon the exact form and dimensions of the apparatus employed. In any case the flash-point of a substance must be regarded as an empirical

---

Vol. 1
constant, but the modification suggested would render the determination less dependent on any particular design of apparatus.

§ 5 HIGH Temperature Flash-point Determinations.—The limiting temperature at which a flash-point determination can be made in the Abel types of apparatus is about 110° F. if the normal procedure is followed. For higher temperatures than this a modification of the normal procedure may be made in that the water bath itself, instead of being set initially to 130° F, is heated continuously throughout the test until a limiting temperature of about 180° F is attained. In addition a small quantity of water is placed in the air jacket to facilitate the rise of temperature of the oil in the oil cup. This method is liable to give discordant results if the rate of heating be too rapid, again owing to the unequal distribution of temperature in the oil cup. Two modified apparatus were introduced to overcome this difficulty and at the same time to extend the range of temperatures over which a test may be made. These apparatus are referred to as the Pensky-Marksen 1 and the Gray 2 flash-point apparatus respectively.

In both these apparatus the water bath is dispensed with and the oil cup is supported in a cavity in an iron casting heated from below. The Pensky-Marksen apparatus has an oil cup similar to that of the Abel-Pensky apparatus, while that of the Gray apparatus is of the same dimensions as the oil cup of the Abel apparatus. The covers in each apparatus differ somewhat in detail, but both are provided with a rotating plate by means of which the ventilation holes are opened and the test flame depressed into the vapour space. Each instrument has a rotary stirrer provided with vanes which agitate both oil and vapour. In carrying out an observation the stirrers are worked continuously between the intervals at which the test flame is applied. The provision of these stirrers ensures that the thermometers indicate the true temperature of the vapour, and in practice it is found that both types of apparatus give sensibly the same flash-point. In carrying out a determination care should be taken that the rate of heating of the oil is slow and regular. The thermometers employed should be calibrated for the degree of immersion obtaining in the apparatus, otherwise it is necessary to apply a correction to allow for the emergent column. This correction is by no means negligible, as under the conditions of immersion in a flash-point apparatus the correction will amount to as much as 15° C at 300° F.

In carrying out the determination of flash-

3 See P. "Thermometry," § (9).

point of an oil the presence of moisture gives rise to considerable uncertainty, and even a small quantity may prevent the oil flashoing until the water has been driven off. The temperature at which this occurs may be well above the normal flash-point of the oil and the resulting flash may be very violent. The drying of oil prior to testing the flash-point is a matter of considerable difficulty, as heating the oil to 100° C. may change it and thereby vitiate subsequent tests. Various methods have been suggested, such as drying with anhydrous calcium chloride or by exposing the moisture-containing oil to a high-tension discharge; none of these methods is entirely satisfactory in removing every trace of moisture, but undoubtedly helps in preparing an oil for a flash-point determination.

§ 6 Ignition Points.—Although not of importance in connection with the legal aspect of flash-point determination, the ignition points of oils are frequently required in connection with internal combustion engine problems. A number of methods have been devised from time to time to carry out this determination without danger to the operator. The simplest form consists in allowing drops of oil to fall upon a heated iron plate. This method has been modified by H. Moore. 3 In this apparatus the iron plate is replaced by a grooved block of steel which may be heated from below in the upper part of the block a cavity is provided into which a platinum or nickel wire is exactly. The crucible is covered by means of a perforated plate, one hole of which permits the introduction of the substance to be tested while the other serves as an inlet for air or oxygen. The gas employed is heated before admission to the crucible by being allowed to circulate through passages in the steel block. In operation the apparatus is raised to a definite temperature and one drop of the oil under examination is allowed to fall into the crucible. If the temperature is above the ignition point of the sample, combustion, more or less violent, takes place, while below the ignition temperature no explosion or flame is observed. Tests are repeated until the lowest point at which ignition takes place is determined.

FLUIDS

FOURIER'S THEOREM

This relates to the expansion of an arbitrary function \( f(x) \) in terms of circular functions of a particular type. Consider, in the first instance, the case where \( f(x) \) is itself periodic, i.e., its value recurs exactly whenever \( x \) has a given constant increment \( a \), so that

\[
f(x + a) = f(x)
\]

for all values of \( x \). The simplest example of this relation is afforded by the circular functions \( \cos(2\pi x/a) \) and \( \sin(2\pi x/a) \), where \( a \) is an integer. The theorem is that whatever the form of \( f(x) \), subject to certain restrictions, it may be approximated to us closely as we desire by a series of terms of the above type, thus

\[
f(x) = A_0 + A_1 \cos \frac{2\pi x}{a} + A_2 \cos \frac{4\pi x}{a} + \ldots
\]

\[
+ B_1 \sin \frac{2\pi x}{a} + B_2 \sin \frac{4\pi x}{a} + \ldots
\]

Assuming for the present the truth of the theorem, the values of the coefficients are found as follows. To find \( A_0 \), which is evidently the mean value of the function, we integrate both sides of (2) from \( x = 0 \) to \( x = a \). This gives

\[
A_0 = \frac{1}{a} \int_0^a f(x) \, dx .
\]

To find \( A_n \) we multiply both sides of (2) by \( \cos(2\pi x/a) \) and then integrate. The coefficient of \( A_n \) in the result is

\[
\int_0^a \cos \frac{2\pi x}{a} \cos \frac{2n\pi x}{a} \, dx
\]

\[
= \frac{1}{a} \left( \cos \frac{2(n+1)\pi x}{a} + \cos \frac{2(n-1)\pi x}{a} \right) dx
\]

Except in the case of \( r = s \) each cosine goes through a complete cycle of its values at least once within the range of integration, and the integral vanishes. When \( r = s \) the result is

\[
A_n = \frac{2}{a} \int_0^a f(x) \cos \frac{2\pi x}{a} \, dx .
\]

By a similar process

\[
B_n = \frac{2}{a} \int_0^a f(x) \sin \frac{2\pi x}{a} \, dx .
\]

For an account of various practical methods of computing the coefficients, and of the mechanical integrators which have been devised to supersede the numerical work, see "Harmonic Analysis," Vol. IV.

There is nothing special to the two points \( x = 0, x = a \), which have been taken as the limits of the above integrations. Any two points at an interval of \( a \) period will give the same result. In particular, writing \( I \) for the half-period, we have

\[
f(x) = A_0 + A_1 \cos \frac{2\pi x}{I} + A_2 \cos \frac{4\pi x}{I} + \ldots
\]

\[
+ B_1 \sin \frac{2\pi x}{I} + B_2 \sin \frac{4\pi x}{I} + \ldots
\]

where

\[
A_n = \frac{2}{I} \int_I f(x) \cos \frac{2\pi x}{I} \, dx, \quad A_n = \frac{2}{I} \int_I f(x) \sin \frac{2\pi x}{I} \, dx ,
\]

and

\[
B_n = \frac{2}{I} \int_I f(x) \sin \frac{2\pi x}{I} \, dx .
\]

This leads to two particular cases of special importance. If \( f(x) \) be an even function of \( x \), so that

\[
f(-x) = f(x),
\]

we have

\[
f(x) = \int_{-I}^I f(x) \, dx
\]

\[
= A_0 + A_1 \cos \frac{2\pi x}{I} + A_2 \cos \frac{4\pi x}{I} + \ldots
\]

with

\[
A_n = \frac{1}{I} \int_{-I}^I f(x) \, dx
\]

\[
B_n = \frac{2}{I} \int_{-I}^I f(x) \sin \frac{2\pi x}{I} \, dx.
\]

Again, if \( f(x) \) be an odd function, so that

\[
f(-x) = -f(x),
\]

we have

\[
f(x) = \frac{1}{I} \int_{-I}^I f(x) \, dx
\]

\[
= B_1 \sin \frac{\pi x}{I} + B_2 \sin \frac{2\pi x}{I} + \ldots
\]

where

\[
B_n = \frac{2}{I} \int_{-I}^I f(x) \sin \frac{n\pi x}{I} \, dx.
\]

In many applications, especially when the variable \( x \) is a space co-ordinate, we are concerned only with a limited range of \( x \), say from 0 to \( l \). As instances we have the vibrations of a string, and the flow of heat through a plate. Outside the above limits the function \( f(x) \) may not exist, so far as the physical problem is concerned, but we are at liberty to imagine it continued analytically both ways as a periodic function. We are further
FOURIER'S THEOREM

at liberty to suppose it continued as an odd or as an even function of \( x \), as is illustrated by the annexed figures. It is to be noticed, however, that in the second case the process of continuation introduces discontinuities at \( x = 0, \ x = a \), unless \( f(x) \) vanishes at these points.

Similarly, in the original form (2) of the theorem, if the function is continued with a period \( a \), discontinuities will be introduced at \( x = 0, \ x = a \), unless \( f(0) = f(a) \).

A complete statement of the conditions under which the theorem (2) holds is not attempted here. For physical purposes it may be sufficient for the moment to say that the expansion is valid provided \( f(x) \) be continuous, and has (within the period) only a finite number of maxima and minima. The mathematical proof, which is necessarily somewhat intricate, must be omitted, but physical arguments of a very convincing kind are easily added. Suppose, for example, that \( x \) is measured along the circumference of a uniform thin metal ring whose total perimeter is \( a \); and let \( f(x) \) denote the initial distribution of temperature. If radiation from the surface be neglected, the theory of conduction of heat indicates that the subsequent process is made up by superposition of the various "normal modes" of approach to a steady state, with arbitrary coefficients, thus

\[
\begin{align*}
A_0 &+ A_1 \cos \frac{2\pi x}{a} - \frac{\lambda \pi}{a} + A_2 \cos \frac{4\pi x}{a} - \frac{\lambda \pi}{a} + \ldots \\
+ B_1 \sin \frac{2\pi x}{a} - \frac{\lambda \pi}{a} + B_2 \sin \frac{4\pi x}{a} - \frac{\lambda \pi}{a} + \ldots \\
& - \frac{\lambda \pi}{a} + \ldots \tag{10}
\end{align*}
\]

This being granted, the initial distribution \( f(x) \) must correspond to \( x = 0 \). Hence \( f(x) \) must admit of expansion in the form (2). Arguments of a similar character might be adduced from Acoustics, and other branches of Physics.

The restriction as to continuity, above made, can to a certain extent be dispensed with. Provided the discontinuities are of finite amount, and occur (within the range of a period) only at a finite number of isolated points, the expansion (2) will still hold except at the points of discontinuity. At such a point the value of \( f(x) \) is of course ambiguous, but it may be proved that the series on the right-hand side of (2) converges to a definite value which is the arithmetic mean of the values of \( f(x) \) immediately to the left and right of the discontinuity. This applies in particular to the discontinuities which may be introduced when a function given over a finite range is continued as a periodic function, in the manner already explained.

Suppose, for instance, that \( f(x) \), is required to express in the form (13) the initial temperature of a conducting slab bounded by the planes \( x = 0, \ x = a \), and, for simplicity, that the initial temperature is everywhere unity. Putting \( f(x) = 1 \) we have

\[
B_n = \frac{2}{a} \int_0^a \sin \frac{n\pi x}{a} dx = \frac{2}{n\pi} (-1 - \cos n\pi) \tag{17}
\]

This is equal to \( 4/n\pi \) or 0, according as \( n \) is odd or even. Thus

\[
1 = \frac{4}{\pi} \left( \sin \frac{x}{a} - \frac{1}{4} \sin \frac{3\pi x}{a} + \frac{1}{8} \sin \frac{5\pi x}{a} + \ldots \right) \tag{18}
\]

When in this case \( f(x) \) is continued as an odd function there is a sudden change from 1 to -1, or vice versa, at \( x = 0 \) and \( x = a \). The series has then the value zero, which is the arithmetic mean aforesaid. The figure shows the approximation given by the first three terms of the expansion. It may be added, in having

\[
\begin{align*}
\lambda &- 2\pi x \sin \frac{a}{\lambda} \ldots \\
\lambda &- 2\pi x \sin \frac{a}{\lambda} \ldots \tag{10}
\end{align*}
\]

\[
\begin{align*}
A_0 &+ A_1 \cos \frac{2\pi x}{a} - \frac{\lambda \pi}{a} + A_2 \cos \frac{4\pi x}{a} - \frac{\lambda \pi}{a} + \ldots \\
+ B_1 \sin \frac{2\pi x}{a} - \frac{\lambda \pi}{a} + B_2 \sin \frac{4\pi x}{a} - \frac{\lambda \pi}{a} + \ldots \\
& - \frac{\lambda \pi}{a} + \ldots \tag{10}
\end{align*}
\]

this topic, that in the applications to physical problems a mathematical discontinuity (e.g. of temperature) is only to be regarded as the idealised expression of a very rapid transition. In practice there is, of course, a limit to
the number of the coefficients $A_r, B_r$, which it is convenient to calculate. The rapidity with which the series converges depends on the smoothness or regularity (in a general sense) of the function $f(x)$. It is evident that the coefficients, as determined by (4) or (5), must ultimately diminish without limit as the order $s$ increases, owing to the more and more rapid fluctuations in the circular functions $\cos(2\pi a/s)$ and $\sin(2\pi a/s)$, and the consequent more complete cancelling of the positive and negative elements in the integrals. More definite results were given by Stokes. If the function $f(x)$, as continued, has only isolated discontinuities, the coefficients ultimately diminish an $1/s$: this is illustrated by (18). If $f(x)$ is everywhere continuous, whilst its derived function $f'(x)$ has isolated discontinuities, the convergence is on $1/s^2$, and so on. The present point has many exemplifications in Acoustics. For instance, the more gradual the initial impulse given to a string, the fainter are the higher harmonics in the resulting note. The approximate representation of an arbitrary function over a given range by means of functions of a specified type is a problem which naturally admits of solution in various ways. It is of interest to note that Fourier's method is the one which makes the sum of the squares of the errors a minimum. Taking for brevity the sine-series (13), and limiting ourselves, in the first instance, to a finite number of terms, the sum of the squares of the errors is

$$\int_0^T \left( f(x) - B_1 \sin \frac{2\pi x}{l} - B_2 \sin \frac{2\pi x}{l} - \ldots \right)^2 dx = 0,$$

(19)

To make this a minimum we must equate the differential coefficients with respect to $B_1, B_2, \ldots, B_m$ to zero. The typical equation is

$$\int_0^T \left( f(x) - B_1 \sin \frac{2\pi x}{l} - B_2 \sin \frac{2\pi x}{l} - \ldots \right) \sin \frac{2\pi x}{l} dx = 0,$$

(20)

where $B_r = \frac{2}{l} \int_0^T f(x) \sin \frac{r\pi x}{l} dx,$

(21)

as in (14). Each additional term included in the series necessarily lowers the minimum, and so improves the approximation, as tested by the method of least squares.

FRICTION

INTRODUCTION.—Friction may be broadly defined as the resisting force which is called into existence at the common boundary of two substances in contact when under the action of some external agency one of the substances slides, or tends to slide, over the surface of the other. The direction of the force of friction is tangential to the surface of contact, and so long as there is no motion of magnitude equal to the component in the direction of motion of the external force tending to produce sliding.

The phenomenon of friction is common to all substances, solid, liquid, or gaseous, which may be in contact with each other and subject to forces tending to cause relative motion, but the laws governing the magnitude of the frictional forces produced, with the magnitude of the external forces acting and the state of motion produced by them, differ widely with the nature of the substances. For example, the friction between the wheels of a locomotive and the rails, in virtue of which railroad traffic becomes possible, depends on the weight on the wheels and not on the speed of the wheels, whereas the frictional resistance of the water to the motion of a ship floating on it depends on the speed of the ship and is independent of the pressure of the water.

The term friction has also been extended, with certain restrictions, the necessity for which will be explained below, to include the mutual resistance which different parts of the same substance offer to sliding over each other. That this interpretation must, of necessity, be extended to fluids is obvious from the consideration that in the case of the skin friction of a ship referred to above, the particles of the water in contact with the surface of the ship are at rest relatively to it, and the sliding to which the resistance is due takes place in the body of the water itself.

The resistance to motion of the ship is, therefore, due to the shearing resistance of the water in which it moves, and for this reason this shearing stress is commonly called the internal friction of the water. In the case of an elastic solid, however, the conditions of relative motion of its particles due to the action of external forces are more complex. For example, suppose a vertical elastic rod is supported rigidly at its upper end and
at liberty to support extremity a mass which or as an even function of oscillations about the by the annexed During each half-oscillation a certain amount of the work done by the rotating mass is stored up as potential energy in the rod and this is given out again to the mass on the return movement. It is found, however, that the amplitude of the oscillations diminishes much more rapidly than would be due to the resistance of the air in which it swings, and it is concluded that frictional resistance have existed in the material of the rod to bring this about, i.e. the rod has a certain amount of internal friction or viscosity. In this particular illustration we have, therefore, a case in which part of the work done against the resistance to distortion is stored up as potential energy of the material and part is converted into heat. That the two phenomena are essentially different will be seen from the fact that in the elastic distortion the resistance is proportional to the relative displacement, whereas in the case of internal friction, or viscosity, the resistance is proportional to the time rate of relative displacement.

The necessity for the restriction of the use of the term friction to those cases in which the work done against the frictional resistance is converted into heat is, therefore, obvious.

From these considerations it will be seen that a more precise definition of friction than that given in the first paragraph would be as follows. The resisting forces brought into existence at the surface separating two substances in contact, or two parts of the same substance, by the action of any external agency tending to produce relative motion at the surface are denominated frictional forces in all cases in which the work done by them is converted into heat.

In previous works on the subject of friction it has been customary to classify all cases of frictional resistance under one or the other of the following two divisions:

(a) Friction between solid bodies in contact; the frictional resistance being subject to certain empirical laws.

(b) Friction between solids and fluids or between solids separated by a film of fluid; the resistance being determined from the motion and physical characteristics of the fluid.

In recent years, however, it has become more and more recognized that this broad division of the subject cannot be made for the reason that it is almost impossible in practice to obtain contact between solid surfaces without the intervention of a contaminating film of fluid which renders the phenomenon one in which the nature of the resistance is to a greater or less extent dependent on the characteristics of the contaminating film.

The modern tendency is, therefore, to regard the frictional resistance of solids in contact and moving relatively to each other as a limiting case of the friction between the solid surfaces separated by a layer of fluid when the thickness of this layer is diminished to such an extent that its motion can no longer be treated by the laws of hydrodynamics, so that the unknown boundary conditions constitute the main characteristics governing the resistance.

For this reason it is proposed in the present article to commence with the treatment of the internal friction of fluids and the manner in which it is affected by the characteristics of the motion, and then to proceed to a discussion of the force acting at a solid bounding surface of a fluid tangential to the direction of the fluid flow, in the first instance when the conditions at the boundary are known, and finally when these conditions are hypothetical.

The detailed classification of the subject-matter of the present article will therefore be as follows:

Division I. Internal Friction, or Viscosity.
Division II. The Nature of the Motion of Fluids over Solid Surfaces and the Characteristics of the Frictional Forces Consequent on the Motion.
Division III. The Determination Theoretically and by Experiment of the Frictional Resistance offered by Solid Surfaces to the Motion of Fluids over them, in all Cases in which the Resistance is determined by the Motion of the Fluid.
Division IV. The Frictional Resistances between Solid Surfaces separated, or Partially separated, by a Film of Fluid of such a Depth that the Fluid does not Conform to the Law of Hydrodynamics.
Division V. The Frictional Resistance of Clean Solid Surfaces.
Division VI. The Relation between Friction and Heat Transmission.
FRICITION 343

assumed by Newton, that for a fluid moving in parallel layers, the shearing stress at any point at which the velocity gradient in a direction perpendicular to the layers was 'de/dy,' would be simply proportional to the value of the gradient, i.e. that the relation between internal friction and the relative motion would be given by

\[ f = \mu \frac{dv}{dy} \]

where \( \mu \) is called the coefficient of viscosity, is a fundamental characteristic of the fluid.

The definition given by Maxwell is as follows:

The coefficient of viscosity of a substance is measured by the tangential force on unit area of either of two horizontal planes at unit distance apart, one of which is fixed while the other moves with the unit of velocity, the space between being filled with the viscous substance.

The interpretation of the coefficient of viscosity of a fluid, according to the kinetic theory of matter, is as follows:

Let AB (Fig. 1) represent the trace of a plane in the fluid, parallel to the direction of motion, and let there be a definite gradient of velocity at right angles to AB as indicated by the lines parallel to AB representing the magnitude of the velocity of the layers relative to the velocity of AB, so that the molecules immediately above AB are moving faster than those below it. Some of these molecules will cross AB from the upper to the lower side and an equal number will pass upwards to replace them. Thus the layer immediately above AB is continually losing momentum and that below continually gaining it. The effect is to bring into existence a definite shearing stress on the plane AB which constitutes the viscous drag. The internal friction of fluids consists therefore of a transfer of motion from one layer to the other, but this transfer does not proceed without loss of energy, since the translatory motion of the layers is transformed into heat. This is evident from the consideration that heat motion differs from translatory motion only in the fact that in the former case particles are moving in all possible directions and in the latter in one and the same direction and that a change from uni-directional motion to multi-directional motion cannot fail to take place in a medium which consists of particles which exert actions on each other by the forces of cohesion or collisions.

§ (2) VISCOSITY OF GASES.—In the case of gases in which the molecules are supposed to be inside the sphere of each other’s attraction during the greater part of the time considered it is possible by means of the dynamical theory to obtain the value of the coefficient of viscosity in terms of the characteristics of the gas.

We picture the gas as composed of a very large number of molecules, moving with varying velocities in all directions and influencing each other by their collisions. Let us consider a group consisting of \( N \) molecules contained in a unit of volume in the form of a cube; then we may suppose, with Joule, that the average velocity at right angles to each face of the cube is the same, so that if \( V \) be the mean resultant velocity and \( u, v, w \) the components we have \( V^2 = u^2 + v^2 + w^2 \); for \( u, v, w \) are equal.

Thus we may regard the gas as consisting of three groups each containing \( N \) molecules and moving with equal velocities \( V/\sqrt{3} \) in the three directions at right angles, or as three groups each containing \( N/3 \) molecules moving with velocity \( V \) in each of the three directions in question. In either case the energy of agitation will be the same.

Adopting this latter view it is clear that considering the whole number of molecules \( N \) in unit volume of the gas, since one-third of this number will be in motion perpendicular to any two opposite faces of the unit cube containing them, and of these half are moving towards either face and half away from it, therefore the number which will be moving from the upper to the lower side of any one face will be one-sixth of the total. Further, considering all the molecules which pass through this face from the upper to the lower side in unit time, it is evident there will be limited to the molecules whose distance from the face at the beginning of the time interval was less than the length of the path which they would travel in unit time. Hence all the molecules which cross the face from the upper to the lower side in unit time come from the prism whose base is in the face and whose height is measured by the velocity \( V \) of the molecules, i.e. all come from a prism of volume \( V \). The number of molecules, therefore, which cross unit area in unit time is in this prism \( \frac{1}{3} NV \). It must be remembered also that each of these molecules has only been moving in a direction perpendicular to the face of the unit cube, since its last collision, and therefore it will only form one of the group during the time which elapses from one collision to another, i.e. over the distance known as the molecular free path \( L \), the average distance travelled by a molecule between two collisions.

Now assuming the existence of a velocity gradient perpendicular to the face of the cube whose value is unity, i.e. that the velocity of flow at a distance \( y \) above the unit face is continuously equal to \( y \) so that according to our definition the friction over the face measures the coefficient of viscosity, and calculate the friction between the two faces separated by the unit face of particles which pass the other per unit of their path toward the face which is eq have described this...

Jouett, "Kinetic..."
Their mean forward velocity is therefore given by 

\[ V = \frac{\mu}{m}. \]

Therefore each molecule carries with it over \( t \) the momentum \( mV \), where \( m \) is its mass, and the total momentum carried over in unit time is \( \mu V m t \).

Simultaneously there pass in the opposite direction across the face \( V \) \( \mu V m t \) molecules, each of which comes from an average distance from the face of \( -V \) and whose mean forward velocity is given by \( V = -V \). The total momentum carried over in this direction is therefore \( -\mu V m t \).

Therefore the layer above the unit face layer in unit time the momentum

\[ \Delta \mu V m t = -\Delta \mu V m t \]

and this, by hypothesis, is the amount of the friction exerted on the face, and is the expression for the coefficient of viscosity. Since \( \mu \) is the density (\( \rho \)) of the gas we may write

\[ \mu = \frac{\mu V m}{V}. \]

If, instead of making the assumption that all the molecules have equal speeds, we assume Maxwell's law for their distribution, it can be shown that a mean atomic value of the coefficient of viscosity is given by

\[ \mu = 6.0057 \frac{\mu}{V}. \]

where \( V \) is the mean value of the speed derived from Maxwell's law. (See Mayer's "Kinetic Theory of Gases," Appendix iv, p. 401.)

Substituting in these equations the value obtained by Clausius for the mean free path

\[ L = \frac{\mu}{\pi a^2} \]

where \( a \) is the radius of the sphere of action of the molecules and \( a \) the volume occupied by a single molecule, we have

\[ \mu = \frac{\mu V m}{4 \pi a^2} \]

and since \( \mu V m = \mu \),

\[ \mu = \frac{\mu V m}{4 \pi a^2}. \]

In this expression for \( \mu \) there is no factor which depends on the pressure of the gas, a deduction from the theory which led Maxwell to predict that the viscosity of a gas would be independent of its density, and that the oscillations of a pendulum in a gas would be equally damped by gaseous friction, however low the pressure might be.

This conclusion was so much opposed to the general opinion of physicists at the time that the experimental verification of Maxwell's prediction, which took place soon afterwards, was perhaps the most important factor in the acceptance by physicists of the kinetic theory. It has been found, however, that when the pressure of a gas is reduced to extremely small values, the viscosity no longer remains constant. This lower limit has been found by Kunik and Warburg to be in the neighborhood of one-sixtieth of an atmosphere. As would be expected, there is also an upper pressure limit at which the law no longer holds, since at high pressures the general assumptions of the theory are not approximately correct.

A further deduction from the kinetic theory as originally developed by Maxwell and Cladius was that the viscosity was proportional to the square root of the absolute temperature of the gas. Experimental investigation, however, failed to establish this relation, and it was found that the natural law of variation of \( \mu \) with \( V \) was given by \[ \mu = \frac{1}{4} \frac{V}{T} \]

where \( \mu \) was found from its lowest value of about \( 2 \) for hydrogen to about \( 4 \) for the less perfect gases. On the assumption that \( \mu \) was equal to unity for all gases Maxwell deduced that the molecules must repel each other with a force inversely proportional to the fifth power of the distance between them. This hypothesis, however, had to be abandoned when it became certain that \( \mu \) was a variable quantity. By a re-examination of the fundamental assumptions on which the kinetic theory was based Sutherland was led to the conclusion that, although the attraction between two molecules of a gas is negligible at their average distance apart, yet, when two molecules are passing quite close to each other, the force of attraction can bring about a collision which in its absence would not have taken place.

On this hypothesis Sutherland has deduced from the equation of the orbit of a molecule that the effect of the molecular attraction in producing collisions is to diminish the mean free path \( l \) in the ratio \( (1 + \epsilon)/\epsilon \), where \( \epsilon \) is a constant for the gas. It follows therefore, from the expression \( \mu = \frac{1}{4} \frac{V}{T} \), that since \( \mu \) varies as \( 1/\sqrt{T} \) and \( l \) varies inversely as \( 1/(1+c/\epsilon) \), the value of \( \mu \) will vary as

\[ \frac{1}{\sqrt{1+c/\epsilon}}. \]

In an experimental investigation into the viscosity of air (see § 9), it was found by Greenly and Gilliland that this relation held with considerable accuracy between temperatures of 0 and 100°, the maximum deviation of the experimental results from the above law being 1.5 per cent.

§ 10. The Experimental Determination of the Values of Components of Viscosity for Flows. (1) Equations of Motion.—As the majority of the methods used to measure viscosity depend on a relation between the motion of the fluid and the variations of the pressure from point to point, a brief account of the derivation of the equations of motion of a viscous fluid is here given.

Assuming the Truth of the Newtonian hypothesis, the equations of motion of the fluid can be obtained as follows: If we imagine three planes to be drawn through any point \( P \) in the fluid perpendicular to the axes of \( x, y, \) and \( z \) respectively, the three components of the stress per unit area exerted across the first of these planes may be denoted by \( p_xp_y \) \( p_z \) respectively; those of the stress across the plane perpendicular to \( y \) by \( p_xp_y \) \( p_z \); and those of the stress across the plane perpendicular to \( z \) by \( p_xp_y \) \( p_z \).

It follows at once that, considering an

\[ \text{"Viscosity of Gases," Phil. Mag., Dec. 1865.} \]
element $dxdydz$ having its centre at $P$, and taking moments.

$$P_x = 3P_{x_1}, \quad P_y = 3P_{y_2}, \quad P_z = 3P_{z_2},$$

Also, if $P_{x_1}, P_{y_2}, P_{z_2}$ be the principal stresses at $P$, it can be shown (a) that:

$$P_{xx} + P_{xy} + P_{xz} = P_{x_1} + P_{y_2} + P_{z_2}; \quad (1)$$

i.e. the arithmetic mean of the normal pressures on any three mutually perpendicular planes through the point $P$ is the same and equal to $\rho$ (say) ; and (b) that the values of the stresses in terms of $\rho$, the coefficient of viscosity $\mu$, and the rates of distortion are given by the expressions

$$P_{xx} = -\rho - \frac{3}{2}\mu \left( \frac{u_x}{c_x} + \frac{u_y}{c_y} + \frac{u_z}{c_z} \right),$$

$$P_{xy} = -\rho - \frac{3}{2}\mu \left( \frac{u_x}{c_x} + \frac{u_y}{c_y} + \frac{u_z}{c_z} \right),$$

$$P_{xz} = -\rho - \frac{3}{2}\mu \left( \frac{u_x}{c_x} + \frac{u_y}{c_y} + \frac{u_z}{c_z} \right),$$

$$P_{yx} = P_{xy}, \quad P_{yx} = P_{xy}, \quad P_{yx} = P_{xy},$$

$$P_{yz} = P_{xy}, \quad P_{yz} = P_{xy}, \quad P_{yz} = P_{xy},$$

$$P_{z_2} = P_{x_1} + P_{y_2} + P_{z_2}, \quad \mu y_z = \mu x_z = \mu y_x.$$  

The condition for "laminar motion"—notion, that is, in which the fluid moves in a system of parallel planes, the velocity being in direction everywhere the same, and in magnitude proportional to the distance from some fixed plane of the system—is seen to be

$$u = \mu x, \quad v = 0, \quad w = 0,$$

from which it follows that the axis of $z$ being taken in the direction of motion and the velocity being proportional to the distance from the plane $xz$.

$$P_{xz} = P_{xz} = P_{xz} = P_{xz} = 0, \quad P_{xz} = \mu x,$$

$\mu x$ being the rate of distortion.

The stresses in different fluids under similar conditions of motion will be proportional to the corresponding values of $\mu$, but if we wish to compare their effects in modifying the existing motion we have to take account of the ratio of these stresses to the inertia of the fluid. From this point of view the determining quantity is the ratio $\mu/\rho$, which is bounded by the special symbol $v$, called by Maxwell the "kinematic" coefficient of viscosity. The equations of motion are obtained by considering the forces acting on a rectangular element having its centre at $P$. Thus, involving parallel to $v$, the difference of the normal pressures is $\frac{\partial P_{xz}}{\partial x}$ and $\frac{\partial P_{xz}}{\partial y}$. The tangential traction on the $x$ face amounts to $\frac{\partial P_{xz}}{\partial x}$, and those on the $xy$ faces are

$\frac{\partial P_{xz}}{\partial y} = \frac{\partial P_{xz}}{\partial y} = \frac{\partial P_{xz}}{\partial y}$.  

If therefore $X, Y$, and $Z$ are the components of the external forces per unit mass, we have

$$\frac{\partial X}{\partial x} = \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x},$$

$$\frac{\partial Y}{\partial y} = \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y},$$

$$\frac{\partial Z}{\partial z} = \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z}, \quad (3)$$

where $\partial X/\partial x$ denotes a differentiation following the motion of the fluid, i.e.

$$\frac{\partial X}{\partial x} = \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x},$$

Substituting the values of $P_{xz}$ etc., given above, we have

$$\frac{\partial X}{\partial x} = \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x},$$

$$\frac{\partial Y}{\partial y} = \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y},$$

$$\frac{\partial Z}{\partial z} = \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z},$$

When the fluid is incompressible, these equations may be reduced to

$$\frac{\partial X}{\partial x} = \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x} + \frac{\partial P_{xz}}{\partial x},$$

$$\frac{\partial Y}{\partial y} = \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y} + \frac{\partial P_{xz}}{\partial y},$$

$$\frac{\partial Z}{\partial z} = \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z} + \frac{\partial P_{xz}}{\partial z},$$

Taking the axis of $z$ to be coincident with the axis of the pipe, and assuming that the velocity is everywhere parallel to $z$, and dependent solely on the distance from the axis, we have $u=0, v=0, w=0$, and therefore from (5)

$$\frac{\partial p}{\partial x} = 0, \quad \frac{\partial p}{\partial y} = 0, \quad (1)$$

i.e., the mean pressure is uniform over each section of the pipe. Again, from (6) we have

$$\frac{\partial p}{\partial z} = \mu \left( \frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} \right),$$

where $p$ is a function of $z$. Transforming into polar co-ordinates $\rho$ and $\theta$

$$\frac{\partial p}{\partial z} = \mu \left( \frac{\partial^2 \rho}{\partial \rho^2} + \frac{\partial \rho}{\partial \rho} + \frac{1}{\rho} \frac{\partial \rho}{\partial \theta} + \frac{\partial^2 \theta}{\partial \theta^2} \right),$$

and, since by symmetry $w$ is independent of $\theta$, the last term on the right-hand side vanishes.
Hence the equation may be written
\[ \frac{\partial}{\partial x} \frac{\partial w}{\partial z} = \frac{1}{\rho \mu} \frac{\partial p}{\partial z} \]  
(4)
or integrating
\[ w = \frac{1}{4\mu} \frac{\partial p}{\partial z} + A \log r + B \]  
(5)
Since the velocity must be finite at the axis, if at 0; and, if \( B \) be determined on the assumption that \( w = 0 \) at the boundary, i.e. there is no slipping at the wall of the pipe (\( r = a \) say), we have
\[ w = \frac{(a^2 - r^2)}{4\mu} \frac{\partial p}{\partial z} \]  
(6)
The flow across any section is therefore
\[ \int w \cdot 2\pi r \, dr = \frac{\pi a^4}{8\mu} \frac{\partial p}{\partial z} \]  
(7)
Thus if \( V \) be the volume passing in time \( T \) so that the flow is \( V/T \), we have
\[ V = T \cdot \frac{\pi a^4}{8\mu} \frac{\partial p}{\partial z} \]
If the full pressure along a length \( l \) of the tube is uniform and equal to \( p_1 - p_2 \), this equation may be written
\[ V = T \cdot \frac{\pi a^4}{8\mu} \frac{p_1 - p_2}{\partial z} \]
If, on the other hand, the possibility of a slip at the boundary is not excluded, the most natural assumption to make is that the slipping is resisted by a tangential force proportional to the relative velocity, i.e. the boundary condition would be
\[ -\frac{\partial w}{\partial r} = \beta w \]
where \( \beta \) is a slipping coefficient, or
\[ w = -\frac{\partial w}{\partial r} \frac{\pi a^4}{8\mu} \frac{p_1 - p_2}{\partial z} \]
This determines \( B \) in equation above, so that
\[ w = \frac{\pi a^4}{8\mu} \frac{p_1 - p_2}{\partial z} \left( 1 + \beta \frac{a^4}{4\mu} \right) \]
If \( \lambda/\mu \) is small, this gives sensibly the same law of velocity as in a tube of radius \( a + \lambda \) on the hypothesis of no slipping. The corresponding value of the flow is
\[ \frac{\pi a^4}{8\mu} \frac{p_1 - p_2}{\partial z} \left( 1 + \frac{4\lambda}{a} \right) \frac{\partial p}{\partial z} \]

§ (4) EFFECT OF TURBULENCE.—It is clear that any experimental verification of the truth of the law of resistance postulated by Newton will depend upon whether in the relation
\[ f = \frac{\partial w}{\partial r} \frac{\partial p}{\partial z} \]  
(6)
a value of \( \mu \) for any given fluid can be found which has an identical value for all values of the velocity gradient \( \frac{\partial w}{\partial r} \frac{\partial p}{\partial z} \). It will be seen later that in these cases of fluid motion in which the motion is turbulent or eddying, the ratio of the shearing stress in the fluid parallel to the mean direction of the flow to the mean velocity gradient perpendicular to this direction is not an absolute constant for the fluid, but depends on the actual values of the velocity of flow and the distribution of the solid boundaries of the flow. In these cases the Newtonian hypothesis breaks down, but its truth under circumstances of streamline flow defined by the condition that the velocity of the fluid at any fixed point is always constant in magnitude and direction has been fully demonstrated. Under these conditions of motion the coefficient \( \mu \) has been shown to be a physical property of the fluid and is known as the absolute coefficient of viscosity.

§ (5) RESULTS OF EXPERIMENTS. (i) Gases.—Most of the earlier determinations of \( \mu \) were carried out by the method of noting the damping of the oscillations of a disc in the gas, as in the case of MAXWELL's chemical experiments. In this method, however, there are considerable mathematical difficulties in determining the motion of the air at the edge of the disc, and in recent work on the subject the method of observing the fall of pressure of the fluid when flowing at a known speed through a channel with parallel walls has been used. An example of this method is seen in the work of GRINDLEY and GIBSON on the viscosity of air. The apparatus used consisted of two gas-holders of about 3 cubic feet capacity connected by a length of lead tubing of 0.125 inch diameter, of which part was used as the experimental tube. The ends of the experimental portion are connected to a manometer by which the fall of pressure can be measured. In commencing an experiment one of the gas-holders contains air and the other water, and by admitting water under pressure to the lower part of the gas-holder containing air, the air is forced through the tube at the desired rate. The gas-holders were calibrated so that the volume of air passing through the tube in a given time could be determined. The length of the tube between the vessels, which was about 100 feet, was wound on a central brass cylinder on a helix of \( \frac{1}{2} \) pitch and 1 ft. diameter. The cylinder rested on supports in a vessel filled with water and provided with devices for maintaining the temperature at any desired value between 0° C. and 100° C. The experimental part of the tube was about 100 feet long.

By inserting the known values of the flow and value of the pressure gradient in equation (6), § (3), the value of \( \mu \) was deduced. It was

found that in accordance with the results of previous investigators the value of \( \mu \) was independent of the pressure, and, further, that its variation with temperature closely approximated to the law deduced by Sutherland from theoretical considerations, so that the value could be written

\[
\mu = \frac{K}{1 + \gamma T}
\]

where \( T \) is the absolute temperature, and, for the case of air,

\[
K = 141.8 \times 10^{-7}, \quad \gamma = 0.026.
\]

For comparison with the results of other observers which are expressed in the form \( \mu = a(1 + bT + cT^2) \), the values of the constants \( a, b, \) and \( c \) for air were found to be

\[
a = 120.5 \times 10^{-6}, \quad b = 0.00299, \quad c = 0.000007.
\]

(6). Liquids.—In forming a physical conception of the viscosity of liquids it is of interest following Maxwell \(^1\) to regard the phenomenon, not as the simple diffusion of matter, but as a limiting case of an elastic solid when the material breaks down under shear. Thus in the case of an elastic solid the shearing stress on any plane is proportional to the space rate of displacement of the material parallel to the plane. The viscous drag is therefore related to the velocity in precisely the same way as the elastic shearing stress to the displacement. We may, therefore, look upon a viscous liquid as capable of exuding a certain amount of shearing stress for a short time and then breaking down and the shear recommencing. If we suppose that the rate at which the shearing stress breaks down is proportional to the shear and is equal to \( \lambda \), where \( \sigma \) is the shear given by \( \sigma = d\tau/dy, \) \( \tau \) being the horizontal displacement, the rate at which shear is applied is \( d\tau/dt, \) or \( d\tau/dy \cdot dz/dt, \) i.e., \( d\tau/dy \cdot v, \) where \( v \) is the velocity of displacement. We have therefore \( \lambda d\tau/dt = d\tau/dy \cdot v, \) and since the shearing stress is given by \( f = \mu \lambda, \) we have \( f = \mu \lambda d\tau/dy, \) or \( f = \mu \lambda v. \) The quantity \( 1/\mu \) is called the time of relaxation of the liquid and measures the time taken by the shear to disappear when no fresh shear is supplied.

§ (6) Early Experiments. (i) Poiseuille’s Method.—The earliest experimenter on the viscosity of liquids was Poiseuille, \(^2\) who carried out a very extensive series of observations on the flow of water through capillary tubes. \(^3\) In these experiments the outlet end of the capillary was connected to a reservoir of water, the pressure in which could be regulated to any desired value by means of an air-pump, connected to the upper cover of the reservoir. Provision was also made for regulating the temperature of the water to any desired value. It was, therefore possible, by using capillary tubes of varying bore and length, to obtain a relation between the rate of discharge, the dimensions of the tubes, and the pressure and temperature of the water. The relation as given by Poiseuille was

\[
Q = \frac{1836 - 724(1 + 0.0336T + 0.000221T^2)}{\mu},
\]

where \( Q \) is the discharge in milligrams of water per second, \( P \) is the pressure difference between the ends of the capillary tube in millimeters of mercury, and \( l \) and \( d \) are the diameter and length of the tube in millimeters. It will be noticed that this relation agrees exactly with the results of the motion of a viscous fluid through a pipe of circular cross-section, on the assumption that the velocity at the boundary is zero, i.e. the time of efflux of a given volume of water is directly as the length of the tube inversely as the fourth power of the diameter and inversely as the difference of pressure at its ends. As an instance of the high order of accuracy obtained in these experiments it may be remarked that the value of \( \mu \) for \( T = 0 \), calculated from the above expression, is in close agreement with the most modern determination. It has been pointed out by Lamb \(^4\) that, if any appreciable amount of slipping at the boundary of the pipes used by Poiseuille took place, a deviation from the law of the fourth power of the diameter would become apparent, and the fact that this was not the case excludes the possibility of such an amount of slipping as has been inferred by Helmholtz and Pietrowski from their experiments on the torsional oscillations of metal spheres filled with water. The question is very fully discussed by Whitham \(^5\) who concluded that no slipping took place.

(ii) Temperature Effect.—It will be seen that the variation of viscosity with temperature is of the opposite sign from that of gases, and it appears to be a characteristic of all liquids that the viscosity diminishes as the temperature rises. In the case of water the change is fairly rapid, as will be seen from the following table, which gives the results of determinations by Hobking:

<table>
<thead>
<tr>
<th>Temp. °C</th>
<th>10</th>
<th>20</th>
<th>30</th>
<th>40</th>
<th>50</th>
<th>60</th>
<th>70</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \mu )</td>
<td>0.089</td>
<td>0.086</td>
<td>0.083</td>
<td>0.080</td>
<td>0.077</td>
<td>0.074</td>
<td>0.069</td>
</tr>
</tbody>
</table>

This rate of variation is in very fair agreement with the temperature coefficient unit determined by Poiseuille and given in the formula above.

(iii) Corrections.—The Poiseuille method, on account of the simplicity of the apparatus required and the ease with which the observations can be made, is still much used, but it should be observed that for accurate work two corrections to the results must be applied.

\(^1\) "Treatise on the Theory of Gases." Phil. Trans. Royal Society, 1851.
\(^2\) Comptes rendus, 1840-41, t. xii. xiii.
\(^3\) Phil. Trans. R.S., lxxxv, 596.
In the first place, the difference of pressure between still water on the inlet and outlet sides of the pipe is not an accurate measure of the pressure gradient along the pipe, since some of this pressure difference is required to communicate to the kinetic energy of motion to the water. Further, in deriving the equation of flow (§ 3), it is assumed that the velocity distribution across the pipe has become uniform and that no accelerations parallel to the axis of the pipe are taking place. This condition is not fulfilled near the inlet end of the pipe, as an appreciable length of the pipe from the inlet in the direction of flow is required in which the accelerations die out and the velocity distribution becomes uniform.

For these reasons instead of the use of the simple formula derived from equation (7), § 3,

\[ \mu = \frac{\pi \rho T}{8V} \left( \frac{p_1 - p_2}{l} \right) \]

where \( T \) is the time of efflux of the volume \( V \) of liquid, \( (p_1 - p_2) \) the pressure difference between the inlet and outlet ends of the pipe, and \( l \) the length of the pipe, the following formula, in which the corrections explained above are inserted, should be used:

\[ \mu = \frac{\pi \rho T}{8V(1 + m^2)} \left( \frac{p_1 - p_2}{l} \right) \]

where \( \rho \) is the density of the liquid under test and \( m \) is a constant. The value of \( m \) may be taken as 1.64 in all cases, and provided that the value of the second term in equation (1) is small compared with that of the first, \( m \) may be assumed equal to unity. Where high accuracy is required it is necessary that the value of \( m \) should be obtained experimentally by a series of viscosity determinations with different rates of flow.

§ 7. Modern Investigations.—In recent work, however, it has been found that no great difficulty is experienced in making an accurate measure of the pressure gradient along the pipe at a sufficient distance from the inlet, provided that the pipe is made of some substance which can be easily machined. In this method two fine holes are drilled in the wall of the pipe at a known distance apart along the axis, great care being taken to prevent a "burr" being formed in the inner surface of the pipe where the hole passes through the wall. Suitable nipples are screwed into the holes at the outer surface and flexible pipe connections made, one to each side of a sensitive manometer. In this way when the flow is set up an accurate measure of the fall of static pressure of the fluid between the holes is obtained. As it is shown that the static pressure is constant along a section of the pipe, the intensity of the frictional force is only calculated formula \( B = \frac{p_2}{2}V \), where \( p_2 \) is the pressure difference per unit area indicated by the manometer and \( V \) is the distance between the holes and \( a \) the radius. This method has recently been used at the National Physical Laboratory for the determination of the resistance to flow of thick oils in pipes. As the method of obtaining the pressure gradient in the pipes in these experiments is novel, a brief description of it is given.

The manometer used was one of the Churck type, the principal of which is that the pressure difference at the two ends of a U-tube is balanced by filling the tube through a small, measured angle so that the "head" due to the difference of level of the fluid in the two vertical arms of the U-tube balances the internal pressure difference, and no movement of the fluid through the tube takes place. For the latter purpose, a telescope is fixed to the fitting table, the level of which is always adjusted so that the line of collimation passes through the surface of the manometer fluid, any water or mercury. It is, however, essential for the elimination of unknown forces due to capillarity that the ends of the manometer tube where the surface of the liquid is situated should be cup-shaped as shown in Fig. 2, and as the detection of the movement of such a large surface is a matter of some difficulty, the device is adopted of introducing a second liquid, usually oil, which will not mix with the water or mercury, into the horizontal limb of the gauge, and the hair-line of the telescope is focused on to the meniscus formed by the common surface of the two liquids. This is the usual device adopted for measuring pressure differences due to the flow of gases through pipes when the static pressure of the gas is small. For measuring the pressure drop in pipes conveying liquids and when the static pressure of the liquids is high, the type of manometer illustrated in Fig. 2 is more convenient. This consists of a U-tube filled with mercury up to the centre of the lower cups, the space above the mercury being filled with salt water. In order to obtain a sharply defined surface of high sensitivity as an indicator of the movement of the mercury, the right-hand cup is connected to a small section and a second cup attached to it as shown. The upper end of this second cup is connected to a reservoir containing a transparent oil which will not mix with the salt water. A side connection to the upper cup is connected with the experimental pipe. The gauge is filled so that the separating surface of the oil and water form a meniscus at the extremity of the contracted part of the lower cup, and on this the hair-line of the telescope is focused. The auxiliary glass-bulb fittings at the sides are

1. Clearly \( F = \frac{B}{2}l \) = total frictional force = difference of thrust = \( p_2 V \).
FRICITION

introduced for convenience in filling the gauge and making sure that no bubbles of air are left in any part of the connections, and in order to obtain a short-circuiting device by means of which the zero of the gauge can be read off without stopping the flow of liquid in the pipe. For the latter observation the two taps in the experimental pipe connections are shut and the tap in the short connecting pipe opened. By this apparatus the frictional resistance to flow was obtained in the case of thick oils of viscosity ranging up to $10^{-3}$ in absolute C.G.S. units.

§ (8) The Effect of Pressure on the Viscosity of Liquids.—In the case of liquids of relatively low viscosity the variation in the value of the coefficient of viscosity with change of pressure is not very marked. The viscosity of water diminishes slightly for pressures of a few atmospheres, and that of benzol and ether increases. Recent researches on the changes of viscosity of certain liquids when the pressure is carried to values as high as 1000 atmospheres have, however, shown enormous increases in viscosity due to high pressures. Thus in the case of alcohol, carbon bisulphide and ethyl alcohol, Professor O. Fauth of Göttingen has found the viscosity of these liquids at pressures of 3000 atmospheres to be more than treble the value at atmospheric pressure. In a recent research carried out at the National Physical Laboratory by Mr. J. H. Hyde, the viscosities of mineral oils at a pressure of 1000 atmospheres were found to have a value exceeding 10 times the value at atmospheric pressure, whereas in the case of a vegetable oil such as rape, the ratio was not higher than 4 to 1. The remarkable character of the rate of rise of viscosity with pressure at the higher pressures will be seen from the curves in Fig. 3, which illustrate the results obtained for castor oil and a mineral oil. As this investigation has an important bearing on the constitution of liquids, a short description of the method used at the National Physical Laboratory for measurements of the coefficient of viscosity at high pressures is here given. The apparatus used for these experiments was designed for carrying out the tests by a method suggested by Dr. E. F. Stanton, and a diagrammatic sketch is shown in Fig. 4. The instrument consists of a U-tube, the limits A and B of which are connected together at their lower ends by a large bore tube and at their upper ends by a capillary tube C as shown. The whole is mounted on a frame supported by a knife-edge D, and so arranged that the left-hand side is heavier than the right. The lower half of the circuit is filled with mercury and the upper half with the liquid under experiment. The motion of the frame is governed by the extension of a spring S, to which it is connected through the supporting arm F terminating in a pointer which moves over a finely divided scale. In making an experiment,
the tilting frame is set in such a way that the horizontal tube are level and the tilt is adjusted so that the pointer is in line with the rim of the annular tube. The tilt is given to the frame by means of the pointer, and the height of the liquid in the tube is noted. The volume of the liquid in the annular tube is then determined by means of the pointer, and the motion which has been given to the pointer is measured from the distance AB and CD. It is clear that the whole of the data required for the calculation of the coefficient of viscosity are available when the dimensions of the annular tube are accurately known, and the value of \( \eta \) is obtained from the formula

\[
\eta = \frac{m \cdot \mu \cdot \rho \cdot T}{L^3}
\]

where \( m \) is the density of the liquid, \( \rho \) the density of the liquid, \( \mu \) the radius of the annular tube, \( T \) the time in passing the volume of liquid through the tube, and \( L \) the length of the tube.

It will be seen that this formula requires knowledge of the viscosity of the liquid with precision before the state of the coefficient of viscosity can be obtained. In the paper by J. H. Hyde and B. W. B. Davies, a method is described in which the viscosity of liquids can be determined by means of which the viscosity of liquids can be determined.

\[ \text{Equation (3)} \]
§ (10) THE VISCOITY OF SOLIDS.—As pointed out in the introduction to this article, the frictional resistance which one part of a solid body offers to the sliding of the other part over it is made up of two distinct phenomena: (1) the elastic distortion of the substance in which the work done is stored up as potential energy in the molecules of the body, and (2) the viscous distortion, the energy of which is converted into heat. It has been remarked by Lord Kelvin that this distinction is not rightly correct, since even in the absolutely perfect elasticity of volume present in homogeneous crystals dissipation of energy is an inevitable result of every change of volume, because of the accompanying change of temperature and consequent dissipation of heat by conduction and radiation. It is, however, recognized that the loss of energy due to this cause is small compared with the whole loss of energy which occurs in many cases of the vibration of metals, so that the statement above may be taken as sufficiently accurate for most purposes. The usual method of studying the phenomena of the viscosity of metals is by noting the rate of damping of the torsional oscillations of long rods carrying a heavy mass at one end and fixed at the other end. The damping of the oscillations is said to be more rapid in glass than in most of the elastic metals such as copper, iron, silver, aluminum, but on the other hand the damping in the case of zinc and indium rather is more rapid than in glass. In the experiments described by Lord Kelvin in the paper referred to, it was found, as would be expected, that the loss of energy in a vibration was greater the greater the velocity, but that the variation with speed was not nearly proportional to the velocity of deformation as in the case of fluids. It would appear, therefore, that the damping is not altogether the effect of viscous resistances of the ordinary type which are proportional to the rates of strain.

§ (11) THE INTERNAL FRICTION OF FLUIDS IN TURBULENT MOTION. (A) RIDDING MOTION.—Before entering upon a discussion of the characteristics of the internal friction of fluids when the general motion is eddying or turbulent, a brief description of the methods of velocity estimation under these conditions is desirable for the reason that a measurement of the mean rate of flow of the fluid through any fixed element of surface taken over an appreciable time is a matter of fundamental importance in the practical determination of the frictional resistance. Since by definition a fluid in turbulent motion consists of a mass of eddies, it might be supposed that any determination of the kind under consideration would be meaningless as defining any physical condition of the fluid, and this is probably true in such cases as those in which eddies, relatively large in size and slow in period, are thrown off from the projecting edges of bodies immersed in fluids moving relatively to them. It has been found, however, that in the majority of cases fluid motion in which turbulence is known to exist either from the fact that the critical speed has been exceeded, or from the observations on the resistance to flow being greatly in excess of those due to streamline motion, the eddies are apparently of such small dimensions and of such high periodicity that any appreciable variation of the forces produced on an immersed body by the turbulent motion of the fluid over it cannot be detected by ordinary methods. For example, if in a parallel channel through which air is in motion above the critical speed, a small open-ended tube be placed with its axis parallel to the axis of the channel and its other end connected to a sensitive manometer as shown in Fig. 5, it will be observed that if sufficient precautions are taken to eliminate external disturbances and irregularities of the mechanism causing the flow, the reading of the manometer remains perfectly steady. Further, if the pressure in the tube be accurately measured it will be found that its value exceeds that of the fluid itself by the quantity \( \frac{\rho}{v^2} \), where \( \rho \) is the density of the fluid and \( v \) is the mean speed of the fluid which would exist over the area occupied by the mouth of the tube if it were removed. The pressure of the fluid itself is usually called the static pressure, and in the case of a fluid in motion, either streamline or turbulent in character, the static pressure at any point is the pressure at the boundary of any smooth solid surface containing the point and parallel to the direction of flow at that point. It is evident that the above relation between the dynamical pressure at the mouth of the tube and the static pressure affords a convenient method of determining the value of the mean speed of a fluid at any point in it.

(1.) THE PITOT TUBE.—In one case of the parallel channel, since it is known that the

* See § (11), (11).
pressure is independent of the radius (see § (g)), all that is necessary is to measure the difference in pressure between the open-
mouthed tube facing the current, commonly called a Pitot tube, and that at a hole in the walls of the channel at the same cross-
section, and equating this to \( \frac{1}{2} \rho v^2 \), the velocity can be calculated. In this way the velocity distribution over the cross-section of a parallel channel may be determined and the total flow calculated by graphical methods. Comparison of the total flow so calculated and that given by a discharge meter at the outlet of the channel has shown that the method can be relied upon to a high degree of accuracy.

For cases in which the flow does not take place in a channel with parallel walls, it is necessary, for the purpose of obtaining the static pressure, to introduce an artificial boundary as close to the mouth of the Pitot tube as possible. One method of doing this is shown in Fig. 6, which is an illustration of the standard instrument used for velocity measurement at the National Physical Laboratory. Careful experiments\(^1\) with an instrument of this type moving in free air have shown that the velocity estimation obtained from it when the pressure differences are measured on a manometer of the Chatteck type have a limit of accuracy of one-tenth of one per cent. In the use of the instrument it is, of course, necessary that the density of the fluid at the point considered should be known, and in the case of a compressible fluid where considerable differences of density exist this may involve another experimental determination of some difficulty.

The original use of the Pitot tube seems to have been for the purpose of measuring the distribution of velocity in rivers and canals. In this form it consists simply of a glass tube bent through a right angle and held vertically in the current, the height of the column of water inside the tube above the surrounding surface being noted. By this means the use of a static pressure tube is avoided, but it is obvious that the velocity estimation must be of only an approximate nature.

(iii) The Critical Velocity.—It was first shown by Osborne Reynolds that, when a fluid was in motion through a parallel channel, there existed a critical value of the mean speed of flow at which the character of the motion changed from one of steady streams parallel to the axis of the channel to one of turbulence in which the whole of the fluid was broken up into a mass of eddies. The causes of the change in the type of motion will be discussed in greater detail in the subsequent sections of this article, but, for the present purpose it is sufficient to remark that the change was found to coincide with a change in the line of frictional resistance to flow through the channel, the streamlined motion corresponding to a resistance varying as the first power of the speed, and the turbulent motion corresponding to a resistance varying nearly as the square of the speed. In the latter case, although the mean motion at any point when taken over a sufficient time is parallel to the sides of the channel, it is made up of a succession of motions crossing the channel in different directions. It is evident that in this case if we are to adhere to the definition of the coefficient of viscosity as the ratio of the shearing stress to the rate of distortion, i.e. that \( f = \frac{\text{velocity}}{\text{distortion}} \), and, further, if \( f \) is taken to express the mean motion taken over a sufficient time, then since \( f \) is known to vary as a power of the velocity greater than unity \( \mu \) must be a function of the velocity and must be held to include the momentum per second parallel to the plane of shear, which is carried by the cross-streams through the plane.\(^2\)

(iv) The Time Viscosities.—If, however, we regard the above relation as expressing the instantaneous value of the intensity of the resistance at a point in the fluid, we must realise that \( \text{constant} \) is the instantaneous value of the rate of distortion, a quantity which we have no means of measuring directly, and that then \( \mu \) is independent of the motion and a physical property of the fluid. It appears therefore that, as pointed out by Osborne Reynolds, there are two essentially distinct viscosities in fluids. One is a physical property of the fluid and is a measure of the instantaneous resistance to distortion at a point moving with the fluid, and the other is a mechanical viscosity arising from the motion of the fluid and given by the relation \( f = \mu \left( \frac{\text{velocity}}{\text{distortion}} \right) \), with \( \mu \) the mean motion at a point taken over a sufficient time, and \( \mu' \) a function of \( \mu \) and probably also of the distribution of the solid boundaries of the fluid.

That these characteristics are independent of each other, apart from the fact of the dependence of the existence of the mechanical viscosity on the physical viscosity, is shown by the striking fact that when the motion of a fluid is such that the resistance is as the square of the velocity, the magnitude of the resistance is independent of the character of the fluid in all respects, except that of its density.

\(^1\) Report of Advisory Committee for Aeronautics, 1912-13, p. 35.
\(^2\) Reynolds, Scientific Papers, II, 236.
§ 12. Measurement of the Mechanical Viscosity. — In a research carried out at the National Physical Laboratory in 1911, the characteristics of the mechanical viscosity of a fluid as affected by the speed and the dimensions of the channel in which the flow took place were investigated. The fluid used was air, which was forced through cylindrical pipes at speeds above the critical, and the distribution of mean velocity was determined by means of a Pitot and static pressure-tube device of the kind described above. In order to simplify the investigation it was desirable that the resistance to flow should vary exactly as the square of the velocity of flow, in which case, as mentioned above, the friction would be entirely independent of the physical viscosity of the fluid. This condition was secured by a suitable roughening of the internal surface of the brass pipes used for the experiments.

The distribution of mean axial speed across the section of the pipe was then measured, and a typical curve of distribution is shown in Fig. 7. It will be seen that the distribution of mean axial velocity in the case of the turbulent motion is approximately parabolic from the axis up to a comparatively short distance from the walls, i.e., the equation to this part of the velocity curve can be written

$$v = v_0 - Ar^2, \ldots \ldots (1)$$

where $v_0$ is the velocity at the axis, $r$ is the radius at which $v$ is measured, and $A$ is a constant.

It was also found that for any section of the pipe the static pressure of the fluid was constant for all values of the radius, so that for any cylinder of fluid of radius $r$ between any two sections distant $l$ apart the shearing stress on the outer surface would be given by

$$f2\pi l = (p_1 - p_2)2r^2$$

or

$$f = \frac{(p_1 - p_2)}{2l} \ldots \ldots (2)$$

where $(p_1 - p_2)$ is the fall of static pressure between the two sections, and $f$ the intensity of shearing stress. The shearing stress in the fluid is therefore proportional to the radius.

But from (1) it is seen that

$$\frac{dv}{dr} = -2Ar,$$

so that the relation $f = \mu'(dv/dr)$ becomes

$$\frac{(p_1 - p_2)}{2l} = -2\mu Ar.$$

Hence $\mu'$, which is the mechanical viscosity, is constant across the pipe up to a relatively small distance from the boundary.

The next step in the investigation was to determine the dependence of $\mu'$ on the rate of flow through the pipe. By taking a series of distributions of axial velocity at different rates of flow and plotting the values of $v/v_0$ on a radius basis, it was found that all the points lay on the same curve, indicating that in equation (1) $v/v_0 = 1 - (Ar)^2$ the value of $A/v_0$ was constant, i.e., that $A$ was proportional to the speed at the axis, and therefore that the value of $dv/dr$ for any radius was simply proportional to the velocity of flow. It follows that, since the shearing stress is proportional to the square of the speed of flow, $\mu'$ must be proportional to the first power of the speed.

Finally, a series of experiments were made with the object of determining the effect of the dimensions of the channel on the mechanical viscosity. For this purpose two pipes of radii $a_1$, $a_2$ were prepared in which the surface roughnesses were geometrically similar, so that the intensity of the surface friction was exactly proportional to the square of the speed of flow. On determining the velocity distributions in these pipes and plotting the values of $v/v_0$ on a basis of $v_0^2$, where $v_0^2$ is the mean square of the pipe, it was found that all the points fell on the same curve, whose equation was

$$\frac{v}{v_0} = 1 - B \frac{r^2}{a^2},$$

where $B$ was a constant.

Now, if $f_1$, $f_2$ are the values of the surface frictions in the two pipes, and $f_1$, $f_2$ the values of the internal fluid friction at corresponding radii $r_1$ and $r_2$,

$$f_1 = \frac{v_0^2 v_0^2}{a_1^2} \text{ and } f_1 = \frac{v_0^2 v_0^2}{a_1^2}$$

$$f_2 = \frac{v_0^2 v_0^2}{a_2^2} \text{ and } f_2 = \frac{v_0^2 v_0^2}{a_2^2}$$

we have therefore

$$f_1 = \mu'_{a_1^2} v_0^2 \text{ and } f_1 = \mu'_{a_1^2} v_0^2$$

or

$$\mu'_{a_1^2} = \mu'_{a_2^2} v_0^2$$

2A

VOL. I

(z - z') is the height through which the air has moved since the last mixture took place.

The average value of \( \omega (z - z') \) can be expressed in the form \( \frac{\partial}{\partial t} \), where \( \partial \) is the average height through which an eddy moves before mixing with its surroundings and \( \omega \) roughly represents the average vertical velocity in place where \( \omega \) is positive.

The movement of the air on the earth's surface as affected by the eddy viscosity may be investigated as follows.

As before, assuming the air incompressible, the equations of motion (see p. 315) may be written

\[
\begin{align*}
\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial x} + w \frac{\partial v}{\partial z} &= \frac{\partial}{\partial x} \left[ \mu \left( \frac{\partial v}{\partial x} \right) \right] + g \cos \lambda - \rho g, \\
\frac{\partial w}{\partial t} + v \frac{\partial w}{\partial x} + w \frac{\partial w}{\partial z} &= \frac{\partial}{\partial x} \left[ \mu \left( \frac{\partial w}{\partial x} \right) \right],
\end{align*}
\]

with the usual notation.

Assume a constant pressure gradient \( G \) acting in the direction of \( y \). The remaining forces are gravity and those due to the earth's rotation.

Hence

\[
\begin{align*}
X &= -2 \omega \sin \lambda, \\
Y &= 2 \omega \sin \lambda.
\end{align*}
\]

where \( \omega \) is the angular velocity of the earth's rotation and \( \lambda \) is the latitude, and

\[
p = k - y p g + G y,
\]

where \( k \) is a constant.

Assuming the motion to be horizontal, equations (1) become

\[
\begin{align*}
0 &= -2 \omega \sin \lambda + \frac{\rho v^2}{\rho} \frac{\partial^2 v}{\partial y^2} \quad ... (3), \\
0 &= -2 \omega \sin \lambda + \frac{\rho w^2}{\rho} \frac{\partial^2 w}{\partial y^2} \quad ... (4).
\end{align*}
\]

Eliminating \( v \) we have

\[
\frac{\partial^2 v}{\partial y^2} + 4B^2 y = 0, \quad \text{where} \quad 2B^2 = \frac{2\omega \sin \lambda}{\rho}, \quad ... (5),
\]

or

\[
v = A_0 e^{-B^2 y} \sin Bz + A e^{-B^2 y} \cos Bz, \quad ... (6)
\]

or substituting in (4)

\[
w = A_0 e^{-B^2 y} \cos Bz - A e^{-B^2 y} \sin Bz + \frac{G}{2B^2}, \quad ... (7). 
\]

At high heights, therefore, \( v = 0 \) and

\[
w = \frac{G}{2B^2 e^{B^2 y} \sin \lambda}, \quad ... (8)
\]

i.e. \( \omega \) is independent of \( y \) and is the value of the velocity calculated from the pressure distribution, and is called the gradient velocity.

The values of \( A_0 \) and \( A \) are found as follows:

Assuming that at the surface

\[
\frac{dv}{dy} = v',
\]

this becomes by substitution from the above relations

\[
\begin{align*}
(A_2 + A_1) &= A_2 + (G/2B^2 y) \quad \text{or} \quad A_2 + Q_0, \quad ... (9), \\
(A_2 - A_1) &= A_2 + (G/2B^2 y), \quad ... (10),
\end{align*}
\]

where \( Q_0 \) is the gradient velocity.

Again, if the wind at the surface be deviated through an angle \( \alpha \) from the gradient wind in such a way that if one stands facing the surface wind the gradient wind will be coming from the right if \( \alpha \) be positive. Then

\[
\tan \alpha = \frac{B}{v}, \quad \text{or} \quad A_1 = -\tan \alpha, \quad ... (10).
\]

Now the surface wind

\[
Q_1 = \sqrt{v^2 + B^2} \alpha - \sin \alpha, \quad ... (11)
\]

This relation has been verified by direct observations made by means of pilot balloons on Salisbury Plain by Mr. G. M. B. Dodson.

Again, if \( H_4 \) be the height at which the direction of the wind coincides with that of the gradient wind, putting \( v = 0 \) we have

\[
A_2 \sin BH_4 + A_0 \cos BH_4 = 0
\]

or

\[
\tan BH_4 = -\frac{A_2}{A_0} \quad \text{and} \quad \frac{\tan BH_4}{1 + \tan \alpha} = \tan \left( \frac{\alpha - \frac{\pi}{2}}{2} \right), \quad ... (12)
\]

Since \( \alpha \) is positive and less than \( \pi/4 \), the smallest positive value of \( BH_4 \) is given by \( BH_4 = 3\pi/4 + \alpha \).

The height \( H_4 \) at which the wind velocity first becomes equal to the gradient velocity is given by \( \alpha^2 + \pi^2 = 0 \), or

\[
-1 \frac{\sin BH_4 - (1 + \tan \alpha) \alpha \sin BH_4}{\tan \alpha} \quad \text{the relation between BH_4, BH_1, BH_0, BH_2, and BH_4 are given in the following table:}
\]

Mr. Dodson gives 800 meters (300 meters \( = 2.68 \)) as the observed value of \( BH_4 \) for
Further, assuming a value for \( c \) of 20°, we have from the above table \( \text{H}_{1} = 2.7 \), and substituting in the relation

\[
B = \sqrt{\frac{20 \sin \lambda \rho}{\rho}}
\]

we find

\[
\rho' = \text{H}_{1} \frac{\sin \lambda}{2.72}
\]

Putting \( \lambda = 0.000073 \) and \( \lambda = 50° \text{N.} \), we have for the South of England

\[
\rho' = \text{H}_{1} \times 0.77 \times 10^{-6}
\]

Taking the values of \( \text{H}_{1} \) from Mr. Dobson's paper, we obtain the following table:

II. THE NATURE OF THE MOTION OF FLUIDS OVER SOLID SURFACES TANGENTIAL TO THE DIRECTION OF FLOW AND THE CHARACTERISTICS OF THE FRICTIONAL FORCES CONSEQUENT ON THE MOTION

§ (14) RESISTANCE TO MOTION OVER A SOLID BOUNDARY.—The relations between the resistance encountered by a solid body moving through a fluid in which it is completely immersed, or by a fluid in moving over a fixed solid surface, can be broadly divided into two classes. The resistance is either proportional simply to the relative speed of surface and fluid, or it is proportional to a power of the relative speed which is in the neighborhood of 2.

(b) The Critical Velocity, Osborne Reynolds' Law.—It is found that these two classes of resistance correspond to two definite states of internal motion of the fluid. When the elements of the fluid follow one another along lines of motion which lead in the most direct manner to their destination, the resistance is proportional to the relative velocity simply. When the particles of the fluid eddy about in sinusoidal paths the most indirect possible, i.e., the fluid is in turbulent motion, the resistance varies nearly as the square of the speed. The transparency of most fluids renders it difficult to determine when a fluid is in steady or turbulent motion. Thus in the case of water passing through a glass tube it is quite impossible by visual examination of the flow to determine which of the states of motion is taking place. A simple method of demonstrating the nature of the motion of fluids and of the manner in which one state of motion will pass into the other was devised by Osborne Reynolds in 1883.* In these experiments a straight tube of glass 5 feet long and provided with a trumpet-mouthpiece was placed in a water tank 6 feet long, 18 inches deep, and 18 inches broad in the manner shown in Fig. 8, and provided with a stopcock to regulate the rate of flow of the water through it. A small reservoir of coloured water was placed above the tank with an outlet into the tank in such a position that a stream of coloured water could be delivered at a very slow speed a few inches in front of the trumpet-mouthpiece, with the result that a streak of the colour could be drawn into the pipe when flow through it took place. The flow of colour was regulated by a clip on the indiarubber pipe connection. It was found that when the cork was slightly opened a streak of colour allowed to enter the pipe with the water, no mixture of the two fluids took place, the streak exhibiting itself as a thin

![Coloured Liquid](image)

**FIG. 8.**

relative values of these terms depend on the value of the ratio \( \nu \rho / \mu \), and it would appear, therefore, that if the eddies were due to one particular cause the birth of the eddies would coincide with some particular value of this ratio.

To test the accuracy of this conclusion, a large number of observations were made in the apparatus shown in Fig. 8 to determine the value of the velocity at which the steady motion broke down in pipes of various diameters.

For the purpose of obtaining the effect of a variation in the value of \( \nu \), the temperature of the water in the tank was varied between the values 5\(^\circ\) C. and 22\(^\circ\) C.

The results of the experiments fully corroborated the conclusions drawn from the equations of motion, the law of the critical point being given by the equation \( \nu d / \rho \mu = 300 \), where \( \nu \) is the critical velocity of flow, i.e. the discharge per unit of time divided by the area of the pipe; \( d \) is the diameter of the pipe, and \( \nu \) and \( \rho \) the viscosity and density of the fluid, all measured in some self-consistent system of units.

(i) Effect of the Boundary.—It was noticed, however, that the critical velocity was much higher than had been expected in pipes of the sizes used, since resistances varying as the square of the velocity had been found at much smaller velocities than those at which the eddies appeared in the tank experiment. Further, it was observed that the critical velocity was very sensitive to disturbance of the water before entering the tubes, and it was only by the greatest care as to the uniformity of temperature of the tank and stillness of the water that consistent results were obtained. This showed that the steady motion was unstable for large disturbances from the critical velocity was reached. As it appeared probable that the cause of this phenomenon was dependent on the boundary condition, the following experiment to show the effect on the motion of an elimination of the solid boundaries was devised. A glass tube 5 feet long and 1\(\frac{1}{2}\) inch in diameter, having its ends slightly bent up as shown in Fig. 9, was half filled with bisulphide of carbon and then filled up with water and both ends corked. The bisulphide was chosen as being a limpid liquid but little heavier than water and completely insoluble, so that the surface between the two liquids could be clearly distinguished. When the tube was horizontal the surface of separation extended along the axis of the tube. On one end of the tube being slightly raised the liquid would flow to the upper end and the bisulphide to the other, causing opposite currents along the upper and lower halves of the tube. It was found that when one end of the tube was raised quickly by a certain definite amount, waves showed themselves at the surface of separation which presented the appearance of wind waves. Further, it was noticed that after the expiration of some days a skin formed slowly between the bisulphide and the water, and that when this was formed a repetition of the tilt did not result in the formation of the waves but in the production of eddies, below and above the surface of separation. It would appear, therefore, that there is a critical velocity independent of the boundary condition, and that the introduction of a boundary condition alters materially the nature of the motion. This conclusion was confirmed by observing the effect of the wind on a surface of water caused by oil drops. It was noticed that as the sheet of oil on the surface of the water drifted before the wind, there was distinct evidence of eddies in the water below the oil at some distance from the windward edge, but that without oil there was no indication of eddies, thus indicating that the boundary condition introduced by the oil was the cause of the eddies. There appeared, therefore, to be no doubt that the break-down of the steady motion in the straight pipe was due to eddies thrown off from the solid boundary, and that, consequently, eddies produced by any other cause such as a disturbance in the water would also tend to bring about the same result. Further, it follows that there must be another critical velocity which would be the velocity at which previously existing eddies would die out and the motion become steady. It was decided by Reynolds to test this conclusion by allowing water in a high state of disturbance to enter a tube and observing the motion at a distance from the inlet considered sufficient for the eddies to have died out if at all.

Obviously the corked end method was useless for the purpose of settling this question, as the effect of adding colour to a mass of water in turbulent motion was to render the whole of it uniform in colour. It was decided finally to investigate the changes in frictional resistance with speed, as it was thought that the speed at which the law of resistance changed from that of the square to that of the first power of the speed might be sufficiently well marked to define a critical speed. For this purpose lead tubes 1 foot in length and a half-inch and a quarter-inch diameter were connected to a supply of water in such a way that the water entered the tubes in a high state of turbulence. The last 5 feet of the tube was connected to a mann-
FRICION

The water flowing from the tube was passed through a special meter, so that all the data for calculating the speed of flow and the frictional resistance were available. It was found that the critical velocity at which the motion changed from one type to another was very clearly marked, both by the violent disturbance of the water in the manometer when the critical velocity was reached, and also by the marked change of slope of the curve of resistance of which the ordinates and abscissae were the frictional resistance and the speed of the water.

As was anticipated, the value of the critical speed thus found was considerably lower than that obtained by the method of colour bands, thus indicating that the critical speed in the latter case had a fictitious value. From the friction experiments it was found that the real critical speed was given by the relation

$$\frac{v_c d^p}{\mu} = 2000.$$

(iii.) Reynolds' Index Law.

Reynolds' method of presenting the results of the experiments was by means of plotting not the observed values of the resistance and speed, but the logarithms of these numbers. It was found that when this process was carried out for any particular pipe the resulting curve consisted of two straight branches, the lower one corresponding to observations below the critical being inclined at 45° and the upper one at a slope to the axis of pressure of n to 1. These curves are shown in Fig. 10 for the case of the two lead pipes used.

It was evident, therefore, that the law of resistance for speeds about the critical was not, as had been supposed, of the form

$$R = \frac{L d}{\mu} + L_0,$$

but of the form $R = C d^m$.

It will be seen later that this relation, known as the index law of resistance, is only approximate, but over the range covered by Reynolds' experiments its accuracy is fairly high.

A general law of resistance for pipes of all dimensions and rates of flow was obtained by Reynolds as follows. From the logarithmic plotting it appeared that $R/R_c = (v/v_c)^n$ where $R_c$ and $R$ are the frictional resistances per unit area at the critical velocity and above it. But since by Reynolds' discovery the

value of $v_c$ is always given by $v_c d^p/\mu = k$, and $R_c$ from the streamline theory is known to be equal to $4 \pi v_c d/\mu$, we have, by substitution,

$$R = \left(\frac{v}{v_c}\right)^n = \left(\frac{v}{v_c}\right)^8,$$

a relation which, according as $n=1$ or a value in the neighbourhood of 2 depending on the nature of the surface of the pipe, expresses the law of resistance for all sizes of pipe and conditions of flow of the fluid. The experiments of Reynolds on which these conclusions are based were carried out in smooth lead pipes of 1.27 and 0.62 cm. diameter, and through a speed range of from 3 to 700 cm. per second for the 1.27 cm. pipe, and from 7 to 400 cm. per second for the 0.62 cm. pipe. Further, a careful examination

of Darcy's very extensive experiments on water flowing in pipes ranging from 2 cm. to 50 cm. in diameter did not show any systematic deviation whatever from the general relation laid down, and with very few exceptions the agreement with the Reynolds formula was within 2 or 3 per cent.

III. The Determination by Theory and Experiment of the Frictional Resistance of Surfaces to the Motion of Fluids over Them

§ 16. Resistance to Motion of a Solid.

The analytical investigation of the resistance encountered by a solid moving through a fluid is one of considerable difficulty. In the early study of the problem, in order to simplify the treatment, the fluid was assumed frictionless. As this method led to the conclusion that the resistance was nil, in order to obtain results more in agreement with the known facts it was assumed that a surface of discontinuity
 existed in the fluid whose boundaries consisted partly of fixed plane walls and partly of surfaces of constant pressure. In this way the resistance of a plane lamina in a fluid, inclined to the direction of flow, was obtained by Lord Rayleigh \(^1\) in the form

\[ R = \rho V^2 \tan \alpha \cos \beta \text{ (tan \alpha \cos \beta) } \]

where \(V\) is the velocity of fluid and \(\alpha\) the angle which the lamina makes with the direction of flow. In this expression the variation of the resistance with the square of the speed has been verified by experiment, but in practice the value of the numerical factor is modified by the existence of a "motion" at the rear of the lamina, which renders the calculated value too small.

Broadly stated, the problem as regards the possibility of solving problems in fluid resistance by the aid of mathematical analysis is that cases in which the motion of the fluid is steady, i.e., streamline in character, are amenable to mathematical treatment, but in cases of free motion the method of treating the motion of a fluid which consists of a mass of bodies has yet been evolved. Since in practical all cases of importance the motion in the neighborhood of the solid bodies is turbulent in character, our knowledge of the resistance to the motion of solid bodies through fluids is largely empirical.

§ (10) Prismatic or Convex Cylinder. Considerable progress has, however, been made in the prediction of the resistance of such bodies as ships and aircraft by the carrying out of experiments on scale models of these bodies in accordance with the principles of dynamical similarity. Thus it has been shown by Lord Rayleigh \(^2\) that the relation obtained by Reynolds for the case of the flow of water in parallel channels is only a particular case of a general law of the resistance of bodies of geometrically similar shape immersed in fluids moving relatively to them, under the assumption that this resistance depends only on the linear dimensions of the body and on the velocity, density, and kinematic viscosity of the fluid. It is further assumed that the geometrical similarity extends to those surface irregularities which determine resistance. If this be the case, the expression for the resistance may be written

\[ R = F(n) \rho V^2 A \]  

(1)

where \(R\) is the resistance per unit area of the body, \(F\) is the linear dimension of the body, \(V\) is the velocity, \(\rho\) the density, and \(n\) the viscosity of the fluid, \(F\) being a dimensionless constant.

The dimensions of \(R\) are \([M][L][T^{-2}][F]\) and the dimensions of the right-hand side of equation (1) are \([L][M][T^{-2}][F]\) \((M[L][T^{-2}][F])\), and by the principle of dynamical similarity these must be identical, i.e., the indices of the respective units must be the same. Equating these we have

\[ c = d = 1 \]

or

\[ c = 4 \text{, } d = 3 \text{, } a = 2 \text{, } d \]

so that

\[ R = \frac{1}{4} \rho V^2 A \]

or generally

\[ R = \frac{1}{4} F_n \rho V^2 A \]

(3)

where \(F\) is a function of the one variable \((V/A)\), \(n\) being the kinematic viscosity of the fluid.

It should be observed that the statement of the truth of this relation is a matter for experimental investigation, as it is quite possible that some characteristics of the fluid or of the motion may have been overlooked in the initial assumptions, such as, for instance, the elasticity of the fluid. Comparing this relation with the experimentally determined relation of Toulousse, Reynolds \((4, 5, 10)\), which may be put in the form

\[ R = k' \rho V^2 A \]

we see that when \(n = 1\), i.e., when the fluid is streamlined in character,

\[ F = k \]

\[ F(n) = k' \rho V^2 A \]

and that when \(n = 1.25\), as in the case of the turbulent flow of water through smooth pipe,

\[ F(n) = k' \rho V^2 A \]

As a result of more general study of the problem of the conditions for similarity of motion of fluids was given in 1878 by H. de Reault \(^4\), of the following which may be quoted. Considering an initial element of liquid of density \(\rho\), fluid viscosity \(\eta\), and dimensions \(x, y, z\), the condition under which the motions of the two fluids are similar is determined by the equation of motion of the first fluid

\[ dp \frac{dx}{dt} \frac{dy}{dt} \frac{dz}{dt} \]

and similar equations, and writing

\[ E x \text{ at } x, \frac{dy}{dt} \text{ at } y, \frac{dz}{dt} \]

then in order that these equations may be true found into the equations for the second fluid

\[ dp \frac{dx}{dt} \frac{dy}{dt} \frac{dz}{dt} \]

\[ \rho' \frac{dx}{dt} \frac{dy}{dt} \frac{dz}{dt} \text{, } \eta' \frac{dx}{dt} \frac{dy}{dt} \frac{dz}{dt} \]

\(^1\) Rayleigh, Scientific Papers, 1, 291.

\(^2\) See article "Dynamical Stability." 

\(^4\) Wallis, Journal, 1878, p. 139.
under the given conditions of similarity
\[ U = \frac{u}{u_0}, \quad V = \frac{v}{v_0}, \quad W = \frac{w}{w_0}, \]

it will be seen that multiplying (1) by \( u^2 p \) the required transformation is effected if the changes in the scales of length, time, and pressure are
\[ X = \frac{X}{u^2}, \quad T = \frac{T}{u^2}, \quad V = \frac{v^2}{u^2}, \quad p = \frac{p^2}{u^2}, \quad \ldots \ (3) \]

It follows, therefore, from the linear scale relation, that if \( L, t \) are corresponding dimensions of two tubes in which fluids of densities \( p_1, p_2 \) and kinematic viscosities \( \nu_1, \nu_2 \) are flowing in order that the two motions may be similar, \( L = \left( \frac{p_1}{\nu_1} \right)^{1/3}, t = \frac{T}{u^2}, \) i.e. \( VL/V \), must have the same value for each. Again, from the pressure scale relation it follows that for similar widest range in the velocities of flow, the linear dimensions of the surfaces, and the nature of the fluids used as would be obtained.

The most convenient method of measuring these conditions, both as regards range in the value of the above characteristics and accuracy in the measurements of the velocity of flow of the fluid and the frictional forces consequent upon it, was obviously that previously adopted by Reynolds, consisting in experiments on the flow through parallel pipes of circular cross-section.

Adapting this method of working, a very complete series of experiments were carried out with air, water, and thick oils as the fluids and with velocities of flow ranging from 30 to 4000 cm. per second. For accurate comparison, as pointed out by Lord Rayleigh, the surfaces of the tubes should have been precisely geometrically similar as regards surface roughness, but as this condition could not be fulfilled the experiments were all made on commercially smooth drawn brass tubes. From the general agreement of the results obtained with different pipes it was not apparent that slight irregularities in this respect had any marked effect on the resistance. The velocity of flow was in all cases taken to be the mean velocity across the section of the pipe. In the case of the pipes of small diameter this was most conveniently estimated by passing the whole of the discharge through a meter and measuring the rate over a given

measured by connecting two holes in the wall of the pipe, one at each section, with a tilting manometer of the Chattock type, by means of which pressure differences as low as one-thousandth of an inch of water can be accurately measured. For the experiments with water flowing through small pipes at speeds from 5000 to 9000 cm. per second, where the pressure drop to be measured was of the order of 50 lbs. per sq. in., specially calibrated Bourdon gauges were employed. These tests gave the highest value of $w_d$ obtained in the experiments—430,000—and the frictional resistance was as high as 18 grammes per square centimetre.

The authors' experiments above the critical speed, i.e., from $(w_d)$ = 2500 to $(w_d)$ = 4700, with the exception of a few individual determinations due possibly to errors of observation, the variation of $R/2a$ for either fluid in any of the five pipes from its mean value does not exceed 2·0 per cent, so that the accuracy of the assumptions in the derivation of the Rayleigh law of resistance is fully demonstrated.

There remained the comparison on the same basis of the results of previous experiments on the flow of fluids in pipes with those obtained at the National Physical Laboratory. These included the very elaborate investigations of Darcy ¹ on the water mains of Paris, a very complete series of tests on the flow of water through drawn brass tubes by Saph and Schadès, ² and the results of investigations by Brix ³ and Stockel ⁴ on the flow of air through lead and iron tubes.

Unfortunately in some of these observations the temperature had not been recorded, so that the values of $v$ could not be calculated with accuracy.

The reduced results were plotted in the same manner as in Fig. 12, and the mean curves through them are shown in Fig. 13, in which the curve for the National Physical Laboratory experiments is also indicated. In the case of Darcy's experiments the curve for the largest pipe is distinct from that of the others, presumably indicating greater roughness of the internal surfaces, but the general characteristics of the curves are what would be expected. For Reynolds' experiments on two smooth lead pipes a mean line has been drawn which indicates a lower resistance than that found in the National Physical Laboratory experiments, but the agreement is quite satisfactory as regards

3. *Phil. Mag.,* 1903, xvii, 482.
The results for the 1.255-cm. pipe were taken, and according to Reynolds' method the logarithms of the friction and velocity from v = 40 to v = 100 cm. per second were carefully plotted. The points as obtained were found to lie on a straight line whose slope was 1.72 to 1. Assuming a law of resistance \( R = C v^n \) where \( n \) had this value, \( C \) was determined from the low speed observations used for the evaluation of \( n \), and a series of values of \( R \) were calculated up to a speed of 3200 cm. per second.

Plotting these calculated values and those actually obtained in the experiments, the two curves in Fig. 14 were obtained, from which it will be seen that by the use of the index law the resistance is underestimated by 5 per cent at 1000 cm. per second, by 8.5 per cent at 2000 cm. per second, and by 15 per cent at 3000 cm. per second.

In order to show the manner of variation of \( n \) throughout the whole range of velocities obtained, the values of \( n \) were taken out by the Reynolds method at four different stages and were found to be:

- Velocity per sec. (cm.)... 58 208 900 2250
- Value of \( n \) from plotting... 1.72 1.77 1.82 1.92

Similar results, showing a gradual increase in the value of \( n \) as the velocity of flow increased, were obtained by the reduction of the observations for the 0.712 and 1.255 cm. pipes, and it was, therefore, fully demonstrated that an index law for surface friction cannot be devised which will express the facts with high accuracy, except over a comparatively small range in the value of \( v \).

The importance of a realisation of this fact when predicting the skin friction of large bodies moving in fluids from observations on small-scale models of them in the same fluid will be obvious.

§ (10) THE EXPERIMENTAL DETERMINATION OF THE FRICTIONAL RESISTANCE OF FLUIDS. (L) -

The determination of these experiments of the frictional resistance of a 1.255-cm. pipe when the velocity ranged from 22 cm. per second, corresponding to the first commencement of eddying motion, to 3150 cm. per second, made possible a check, within these limits, of the accuracy of the well-known index law of resistance due to Reynolds and Founde.

1 Proc. R. S., 1014, A, xcf.
surface which includes that part of it over which the particles of fluid are being gradually retarded—i.e. the part in the neighbourhood of the leading edge of the surface such as, for example, the immersed surface of a ship. For the prediction of the skin friction of ships special experiments are necessary, and a large series of very important observations were carried out by Mr. William Troude in 1872-74.\(^1\) These experiments were made in a water tank 278 feet long, 30 feet wide at the top, the depth of the water being 8 feet 9 inches. The boards of which the frictional resistance was determined were about ¾-inch thick, 10 inches deep, the top edge being 1½ inches below the surface. The length varied from 1 foot 6 inches to 50 feet.

The experimental apparatus (Fig. 16) consisted of a carriage running on rails fixed to the walls of the tank and capable of being drawn along at a uniform rate. A parallel motion suspended from the carriage carries the board, which is provided with a lead feel and a cut-water. The frictional resistance of the board is taken by the spring shown, the extension of which is magnified and transmitted to a recording drum on which a line is drawn whose distance from the base is proportional to the distance from the origin, but at all speeds were concave to the base.

In this way a series of curves (Fig. 16) was obtained for each length of board and from these curves a series of values of resistance for different speeds could be deduced. In the first experiments the latter curves did not pass through the origin, but above it, showing that the resistance was not zero for zero speed. It was found to be due to the bluntness of the bow and stern of the board. On shaping these to knife-edges it was found that the curves passed through the origin, however, that the curves were not straight but at all speeds were concave to the base, indicating that the resistance did not vary as the length but at a less rate. This result is due to the fact that the portions of the surface down-stream from the leading edge are in contact with water relative to them is less than that of the other portions nearer the edge.

It was found that for a given plank the resistance varied as \(n^2\), where \(n\) was constant but in different planks depended on the length and quality of the surface. The value of \(n\) is found by

Friction the effect of curvature of parallel boundaries have been made by Mr. A. Mallock. In these experiments the fluid was placed in the annular space between two concentric cylinders, one of which revolved, the other being stationary. The frictional resistance of the surface was measured by measuring the moment on the stationary cylinder which would be either the inner or the outer one.

Three distinct sets of conditions were tried, i.e. (1) outer cylinder revolving, inner cylinder stationary; (2) inner cylinder revolving, outer cylinder stationary; (3) repetition of series (1) with an annulus of different width.

The arrangement of the apparatus for the tests on series (1) is shown in Fig. 10.

The inner cylinder A is suspended by a tension wire attached by a gimbal ring to the shaft B, which carries a divided circle read by a telescope T. E is the outer cylinder carried on the shaft F, which is driven by a motor provided with a speed regulator. A is filled with water and E is jacketed, the temperatures of both being observed and the temperature of the fluid in the annulus taken as the mean of these. The cylinder A has its floor about half an inch from the lower edge of the wall, and the space so formed is filled with air. Further, by means of a ring of the same diameter as A fixed to the floor of the outer cylinder, and by filling the annular space between the ring and cylinder with mercury, there is comparatively no drag on the water in the annulus due to the bottom of the outer cylinder.

In the case of the first series of experiments, with the outer cylinder revolving and the inner one stationary, the results were similar to those obtained in straight pipes, i.e. the friction was proportional to the speed up to a certain critical velocity, at which the motion broke down and steady readings of the friction were impossible to obtain, the conditions becoming steady again at higher values of the speed. This is shown in Fig. 20. The results, however, differed fundamentally from those obtained in straight pipes in that

(a) The critical velocity was not proportional to the value of the coefficient of viscosity, i.e. its value did not conform to the theoretical condition \( \eta = \text{constant} \).

Thus, comparing the results obtained with water at 50°C. and 0°C., the viscosity of water at 50°C. is only one-third of its value at 0°C., and it would be supposed therefore that the critical velocity at 50°C. would be one-third of its value at 0°C. It was found, however, that instability began at the former temperature at a speed only 11 or 12 per cent less than at the latter.

(b) It was found that at speeds above the critical the frictional resistance varied as a power of the speed of the order of 2-4, whereas in Reynolds' and Frome's experiments with flat boards and pipes the exponent was about 1-8.

Values of the coefficient of viscosity deduced from the low-speed experiments in series (1) were found to be consistently higher than the true values. The experiments of series (3), in which the width of the annulus was only half an inch, gave values of \( \mu \) which were nearer to the true value. Previous experiments by Mr. Mallock, by the same method but in which the distance was only about \( \frac{1}{4} \) in., gave values of \( \mu \) closely approximating to the true value, so that there is no doubt that the discrepancy is due to the thickness of the annulus. The results are shown in Fig. 21.

In the experiments with the inner cylinder revolving and the outer cylinder fixed, the motion was essentially unstable at all speeds, and no value of the coefficient of viscosity could be deduced. The results from this method are shown in Fig. 22, and indicate that the conditions of flow approximate more closely to the eddying flow of fluid.
FRICITON

resistance with increase of viscosity, is now a large fraction of the whole curve, and constitutes perhaps the most important evidence of the effect.

It would appear, therefore, that the existence of particular states of flow in fluids, in which an increase in viscosity is accompanied by a reduction in resistance, has been fully demonstrated. The precise explanation of the phenomenon is not clear, but there is a strong probability that the increase in viscosity has the effect of reducing partial and already existing turbulence, and thus producing a recession to the conditions of streamline flow.

§ (23) DIRECT MEASUREMENT OF FRICTIONAL RESISTANCE FROM VELOCITY SLOPE AT THE BOUNDARY.—From the preceding discussion of the practical methods which can be used for the measurement of skin friction in turbulent motion, it will be seen that any accurate determination of the intensity of skin friction on a small area of a surface over which the variation is considerable is a matter of considerable difficulty if not altogether impossible. Up to the present, success in the measurement of skin friction has only been attained in those cases in which the accelerations of the fluid in the direction of flow have died out, such as the flow of fluids in long pipes. Unfortunately, the problems of skin friction, which are of the greatest importance in practice, such as the determination of the frictional resistance of ships and aircraft, are those in which the velocity of the fluid is continually changing, and it does not appear that the solution of these problems can be hoped for unless the conditions at the boundary of a fluid in turbulent motion are known, and several attempts to investigate these conditions have recently been made. Such advances as have been made in the knowledge of the boundary conditions of a fluid in turbulent motion have been obtained, as would be expected, from a study of the conditions of flow in parallel pipes. In such flow it is generally accepted that when the speed is below the critical, the layer of fluid in contact with the boundary is at rest relative to it, as any slipping of finite amount would be detected.
in straight pipes in that the friction varies as a power of the speed of about 1/8, and the measured value of the resistance per unit area at 10 feet per second was roughly that obtained by Mr. Frnicle in his experiments on plates.

§ (23) VISCOITY OF AN INCREASE IN Resistance Caused By A Reduction in Viscosity.—In the practical application of the results of the experiments embodied in the curve of Fig. 12, it must be remembered that there was one important condition which was fulfilled in every case, which was that the observations were not taken until the distribution of speed across the section of the pipes had become uniform, i.e. all accelerations parallel to the axis of the pipes had ceased. It was found by trial that this condition was not fulfilled until a distance along the pipe from the inlet of about 100 diameters was attained. The results of the experiments are therefore not applicable to the prediction of the intensity of surface friction of the part of the tube in the neighbourhood of the inlet, when the layers of fluid in the neighbourhood of the surface are gradually reduced in speed owing to the frictional drag of the surface.

Further, although it might be expected that, in the case of solid surfaces of shapes other than those of parallel channels, the phase of flow would correspond with those observed in pipes, i.e. there would be a phase of streamline flow in which the resistance would vary as the first power of the relative speed, a critical velocity at which this form of flow would break down and a subsequent expansion of turbulent motion in which the resistance would vary approximately as the square of the speed, it cannot be assumed that the form of the resistance curve will be similar to that of Fig. 12. For example, throughout the whole range of the turbulent motion covered in Fig. 12 the value of R/pu² falls continuously as v/ρu increases. Suppose this increase is due to an increase in τ from v to vo remaining constant. Then it is clear that R/τ increases at a less rate than (v/ρu)², or R/σ/(σν²v/ρu)², where n is less than 2. Suppose, on the other hand, that the increase in ρu² takes place by a reduction in the value of v from v to vo remaining constant. Then evidently R/σ is less than R/σ, and we conclude that throughout the whole range of turbulence covered in Fig. 12 a reduction in viscosity is accompanied by a reduction in frictional resistance. Very conclusive evidence has, however, been found that in some cases of the resistances of bodies used in fluids the value of R/ρu² increases as ρu². It is evident that, in cases, since the increase in ρu² may take place by a reduction in the value of v, ironing constant, and therefore R/σ being numerically greater than R/σ, a reduction in viscosity will be accompanied by an increase in the frictional resistance. Further, since in such cases R/σRₙ=(σν²v/ρu)², where n is greater than 2, the criterion of such an effect will be a resistance varying as a power of the speed greater than 2. The following are some examples:

(a) Friction in Smooth Pipes.—As was mentioned in the description of Reynolds' experiments, it is usually found that over the region intermediate between turbulent and steady motion the friction conditions are so unstable that consistent readings at any given speed are impossible. In some observations with a small pipe of 1 in. diameter, at the National Physical Laboratory in 1913, it was found, however, that the change from streamline
(c) The slopes of the tangents to the velocity curves at distances of 0·75 mm. and above from the walls are very much smaller than would be the case if the flow were laminar at those distances from the wall.

(d) The speed calculated from the observations at a distance of 0·75 mm. and less from the walls are appreciably higher than would exist in laminar flow with the measured surface friction. For example, with a frictional resistance of 10 dynes per sq. cm., the calculated speed at 0·75 cm. from the walls was 705 cm. per second. In laminar flow with this value of the surface friction the speed would be 443 cm. per second.

It appeared, therefore, that if in these experiments it could be assumed that the speed indicated by the Pitot tube was the speed of the fluid at its geometrical centre the streamline motion, if it existed, was confined to a region of less than 0·75 mm. from the boundary, and, further, the observations were not inconsistent with a finite amount of slip at the boundary. It was evident, therefore, that the proof of the existence or otherwise of streamline motion at the boundary would involve a much closer examination of this region than had hitherto been possible. As any further reduction in the cross dimensions of the Pitot tube would have rendered it unworkable, a modification of the shape of the tube was considered, and it was decided to try experiments with a tube in which its boundary adjacent to the wall of the pipe was removed and its place taken by the wall of the pipe itself. This modification is shown in Fig. 28.

As the space occupied by this tube was considerably less than in the four-walled one, it was decided to fit a Pitot tube of this form to a pipe of 0·25 cm. diameter. The reason for choosing such a small pipe was that the critical velocity in it would be so high that it would be possible to take a series of observations at about 0·1 mm. from the wall at speeds of flow below the critical, in which cases the actual distribution of velocity across the tube was known to be parabolic, and compare these values with those deduced from the Pitot tube readings. In this way the relation between the geometrical centre of the Pitot tube and its effective centre could be determined, and the possibilities of error pointed out in (a) and (b) above would be avoided.

A series of tests were accordingly made at a given value of the mean rate of flow below the critical, and at different distances of the geometrical centre of the modified Pitot tube from the wall. From the equation of the distribution of velocity in streamline flow \( v = v_0(1 - r^2) \) the values of \( r \) were calculated for each value of \( v \) calculated from the observations.

Points were then plotted whose ordinates were the values of \( (r-1) \) and whose abscissae were the corresponding distances of the geometrical centre of the Pitot tube from the wall.

This process was repeated for different values of the mean flow all below the critical value, and the mean curve through all the plotted points was taken to be the calibration curve for the Pitot tube. This curve is shown in Fig. 29. It will be seen that for openings of the Pitot tube of the order of 0·3 mm. the assumption that the calculated speed is that which exists at the geometrical centre of the orifice is not greatly in error, but that when the opening is of the order of 0·75 mm. the interference with the flow is so considerable that the calculated speed is that which exists at the edge of the Pitot tube further from the wall.

A series of observations were then made all at a speed above the critical and with the centre of the tube at different distances from the wall. The speeds calculated from these observations are shown plotted in two methods in Fig. 30. On the left-hand side of the figure the abscissae of the points are the distances of the centre of the Pitot tube from the wall, and on the right-hand side the abscissae are the "effective distances" as reckoned off from the calibration curve of Fig. 29. Assuming that this calibration curve can be applied to conditions of flow above the critical, which seems reasonable in view of the fact that the amount of turbulence at the distances in question must from the evidence of Fig. 27 be very small, the curves on the right of Fig. 30 show the velocity distribution near the wall when the readings of the Pitot tube are corrected for interference.
in a variation from the Poiseuille law of the relationship between the diameter of a pipe and the time of efflux of a given volume of fluid. At speeds above the critical, observations near the walls have shown that the mean velocity falls rapidly as the solid bounding surface is approached, and it has been suggested that at the walls there may exist a thin layer in which the flow is laminar in character, in which case, if there is no slipping, the frictional resistance would be determined from the slope of the velocity curve in the surface layer and the coefficient of viscosity of the fluid. Several attempts have been made at the National Physical Laboratory to obtain evidence as to the truth of this assumption, and a series of experiments were carried out in 1920, the results of which afford strong evidence that such a layer exists. The method adopted was to set up a condition of turbulent fluid motion over a surface of which the frictional resistance could be accurately determined and to measure, by means of a very fine Pitot tube, the velocity of the fluid at a point as near the wall as possible. The difficulties of using a Pitot tube under such conditions were: (a) that the pressure indications of the Pitot tube might be considerably affected by an interference in the flow in the neighborhood of the boundary due to the presence of the tube itself; and (b) that when such a tube was placed in a current of fluid in which the variation of velocity across the mouth of the tube was very great (amounting in the extreme cases when the tube touched the walls to several hundred per cent of the mean speed), it was by no means certain that the value of the speed deduced from the pressure in the Pitot tube would be the actual speed at the geometrical centre of the tube. The Pitot tube, which was finally adopted for the work, was one of which the external dimensions at the orifice were 0.1 x 0.8 mm. and the internal dimensions 0.06 x 0.75 mm. This was set up in a pipe of 0.314 cm. diameter, through which a current of air was passed by means of a centrifugal fan, and observations of the Pitot tube pressure were taken over an wide a range in the mean rate of flow through the pipe as possible. At the same time the corresponding slopes of the static pressure gradient down the pipe were accurately determined. From the latter measurements the values of the surface friction of the walls for different rates of flow were calculated. The Pitot tube observations were then repeated for other distances of the tube from the walls. For each distance a curve of speed variation with surface friction was plotted, and from these curves it was possible to scale off, for any given value of the surface friction, the speeds corresponding to the different distances of the Pitot tube from the walls and to plot a curve showing the variation of speed with position of Pitot tube. These curves are shown in Fig. 26. In the same figure are shown in dotted lines the velocity slopes which would exist at the boundary if the flow were laminar. These are calculated from the known frictional resistances and the value of the coefficient of viscosity for air.

To show the relation between surface friction and the speed at a point near the wall, the corresponding observations were reduced by the Reynolds method of logarithmic plotting previously described, as shown in Fig. 27. These plottings show that the relation between surface friction and speed at a point is of the same form as for surface friction and mean flow, i.e. \( F = C v^2 \), but that the value of \( C \) diminishes as the boundary is approached until when the geometrical centre of the Pitot tube is 0.75 mm. from the wall the value of \( C \) is 1.16. It would appear, therefore, that at this distance the eddy motion has nearly disappeared.

On examining the curves in Fig. 26, and assuming the pressures mentioned under (c) and (b) above are negligible, the following characteristics will be noted.

it is of fundamental importance to know at what speed a ship of given lines will be propelled by engines of a given horse-power, and also to have some reliable means of estimating the benefit which may be derived from a change of lines. The problem of the prediction of ship's resistance $r$, however, complicated by the fact that a considerable proportion of the total resistance of a ship may be due to the formation of waves on the surface of the sea and that this component cannot be estimated by the application of the law of comparison $\text{friction constant}$. A law of comparison for both friction and wave-making may be derived by the ordinary dimensional reasoning, remembering that, in addition to the velocity, density, and viscosity of the fluid, and the linear dimensions of the solid, the acceleration of gravity must also be taken into account, i.e. we have

$$R = \frac{\pi^2 \rho^2 \nu^4 \rho}{a^3}$$

or the dimensional equation

$$\left[ \frac{\text{M}L}{T^2} \right] = \left( \frac{\rho}{\Gamma} \right)^a \left( \frac{M}{\Gamma_0} \right)^b \left( \frac{L}{\Gamma_0} \right)^c \left( \frac{T}{\Gamma_0} \right)^d \left( \frac{\rho}{\Gamma_0} \right)^e$$

from which

$$b = 1$$
$$c + d + 2e = 2$$
$$a - 3b + c + 2d + e = 1$$

or $b = 1, a = 2 - d + e, c = 2 - d - 2e,$ from which

$$R = \frac{k \nu^2}{T} \rho \nu^2 = \frac{\nu \rho \nu^2}{\nu \nu}$$

or

$$R = \rho \nu^2 \nu^2$$

In order, therefore, that the total resistance of a ship may be accurately predicted from the measured resistance of a scale model of it, the following relations must hold:

$$\nu = \frac{VL}{I}$$
$$\nu = \frac{N}{I}$$
$$\nu = \frac{N}{I}$$

where the capital letters refer to the ship and the fluid in which it is immersed and the small letters to the model and the fluid in which it is moved. The condition is therefore $N/\rho = V/L/\rho = (\rho \nu)^2$.

Assuming $\rho = 25$, it would be essential, for the condition to be fulfilled, that the model should be moved in a fluid whose kinematic viscosity is less than 1 per cent of that of sea-water, which, of course, cannot be realised. For this reason the method adopted in practice is to separate the wave-making resistance from the frictional resistance in the following manner. It is clear from equation (4) that if friction be neglected the wave-making resistance of a ship is given by

$$R_m = \rho \nu^2 \rho^2 \left( \frac{L}{\nu} \right)^2$$

If, therefore, we determine the wave-making resistance $r_w$ of a scale model of a ship under the condition that the quantity $\nu^2 \rho^2$ is the same for the ship and the model, we have

$$r_w = \frac{VL^2}{I^2} - \frac{L^3}{I^3}$$

i.e. the wave-making resistances of ship and model are in the ratio of the respective displacements. The procedure adopted is to carry out a test in a water-tank of a scale model of the ship at a speed given by $\nu^2 \rho^2 = \frac{VL^2}{I^2}$ and determine its total resistance $r$. By means of tables of frictional resistances based on Prandtl's tests on the frictional resistance of thin planks the value of the frictional resistance $r_f$ of the model at a speed $\nu$ is calculated and we then have $r_w = r_f - r$. The wave-making resistance of the full-sized ship is then given by equation (6)

$$R_w = r_f \left( \frac{L}{I} \right)^2$$

The frictional resistance of the ship is then calculated from the available data and its value $R_f$ is added to $R_w$ to make up the total resistance of the ship.

The objection to the use of data obtained from experiments on thin plates, for the calculation of the skin friction of ships, will be obvious from the consideration that the distributions of the fluid motion in the two cases are widely different. This is particularly marked in the case of the ship's stern owing to the marked tendency of the streams after passing the midship section to separate from the lines of the ship, leaving a wake of eddies at the stern moving at comparatively low speed. This effect is well brought out in the photographs shown in Fig. 31. These photographs represent the flow of water round small model balloons of varying fineness of tail. In order to render visible the flow in the region of the tail the model was given a thin coating of colour which would gradually dissolve away as the water flowed past and by the extent of its admixture with the water streams would give an indication of the motion. It will be seen that in each case there is a dead water region at the tail, the extent of which increases with the bluntness of the tail, and since it also increases with the speed of flow, it is probable that the region will be large even in the case of a fine-tailed balloon of normal size and at normal speed. Corresponding effects will take place in the case of a ship unless the lines are particularly fine.

§ (25) The Estimation of the Friction of the Tides.—From the curve of Fig. 12
It will be seen that the effect of the correction for interference is that at distances of the order of 0.05 from the wall the slopes of the velocity curves approximate fairly closely to the values which would exist in laminar flow. Further, there is no indication of the existence of any slip at the boundary. The conclusion was, therefore, that very definite evidence had been found of the existence at the boundary of a fluid in turbulent motion, of a finite layer of fluid in laminar motion and having zero velocity at the boundary. This evidence was supported by similar observations made on a large pipe of 12.7 cm. diameter, and very large rates of flow, and, although a rigid demonstration was out of the question, and, since all the terms on the right-hand side are supposed known, the equation is determinable. If, therefore, the linear dimensions of the model are such that no experiment for the purposes of estimating its resistance can be made upon it, the comparison made above opens up a possibility of predicting this resistance from an experiment on a small scale model of it in a laboratory.

In practice the use of this method is limited by the fact that the necessary conditions to be fulfilled in the model test are nearly always impossible to realise. For example, if it is required to predict the resistance of an aerofoil 200 feet long at 60 feet per second and a model of the ship to a scale of 1 in 372 is available for the experiments, then suppose this test to be made in air, we have $v_1 = v_2$, $l_1 = 10l_2$, and therefore $v_2 = 10v_1 = 600$ feet per second, a condition which could not be realised in a laboratory experiment. Suppose, however, the model experiment be made in water. Then we have $v_1 = 13v_2$, $l_1 = 10l_2$, and since $v_1l_1/p_1 = v_2l_2/p_2$, we have $v_2 = 46$ feet per second. This condition, again, is one which could hardly be realised in water tanks with submerged models, but it will be clear that the possibilities of a prediction are greatly increased. If we could obtain a fluid whose kinematic viscosity was only 1 per cent of that of air, the model test could be made at a speed of 6 feet per second and the prediction could probably be made.

Unfortunately no such fluid is available, so that a direct solution of the problem is not to be hoped for. The importance of scale model tests, however, is not thereby negatived, since a study of the variation in the value of $R/p_d^2$ over the range in which scale model tests are possible often renders invaluable help in the prediction of the manner in which it will probably vary outside this range. This will be seen from a study of the curves of variation of $R/p_d^2$ with $e/l_d$ in Figs. 12, 24, and 25. In each of these cases it will be seen that for high values of $e/l_d$, which are those of practical importance, the curve appears to be tending to a definite limiting value, which may be used, with probably fair accuracy, as a basis of prediction in design.

(II.) Ship Resistance. — One of the most important applications of model experiments is the prediction of the resistance of ships, since

$\frac{R_2}{R_1} = \frac{\rho_2 v_2^3 l_2}{\rho_1 v_1^3 l_1}$
It will be seen, therefore, from reference to the curve in Fig. 12 that the limiting value of the ratio $R/p$ obtained in laboratory experiments on pipes when the velocity or the linear dimension is large, may also be applied with fair accuracy to the calculation of the skin friction of the wind on the earth's surface.

* The definition of the coefficient of friction is tabulated above as—Coefficient of friction multiplied by the total load—moment of friction divided by the radius of the journal.

§ (27) The Frictional Resistance of Surfaces Separated by a Thin Layer of Fluid. (1) Cylindrical Surfaces, Tower's Experiments.—It was discovered by Mr. Barlowe and Mr. Town in 1883 in the course of some experiments made for the Institution of Mechanical Engineers, that in the case of a lubricated bearing resting on a revolving shaft, the surfaces of the shaft and bearing were completely separated by a thin film of oil under pressure, and that the component of the total fluid pressure in the direction of the load was numerically equal to the load.

Town's apparatus consisted of a half-bearing of brass resting on a shaft 4 in. in diameter, the lower part of the journal being always immersed in oil. Arrangements were made to measure the frictional resistance of the bearing, the speed of the shaft, and the temperature of the oil for various conditions of loading. Further, by inserting pressure holes at various points in the surface of the bearing and connecting these to a manometer, he obtained an approximate solution of the problem of the half-bearing, the results indicating that it was essential for the maintenance of the film that there should be a difference between the radius of the bearing and that of the journal, the two surfaces having a given eccentricity depending on the load, conditions of running, and the nature of the lubricant. It was further shown by the theory that this position of nearest approach was not in the line of action of the load, but that the relative position of the two surfaces would be somewhat as shown in Fig. 32, the position of nearest approach being what was termed by Mr. Tower the "off" side of the line of load, i.e., the side of recession of the journal surface from the line of load as distinguished from the "on" side or side of approach.

Thus, starting from the condition of no load, the distribution of the vertical and horizontal components of the pressure of the oil film...
It will be seen that for very high values of \(v/\mu\) the value of \(R\mu^2\) tends to a definite limit whose value is not far removed from \(-0.02\).

An interesting calculation has recently been made by Mr. G. I. Taylor \(^1\) which indicates that this value may also be applied to the frictional resistance caused by the movement of the tides over the bottom of the sea. Assuming the frictional resistance per unit area is to be given by \(k\mu^2\), the energy dissipated per square centimetre per second is \(k\mu^2\). Now the tidal stream at any time \(t\) after it has attained its maximum velocity may be taken roughly as \(V = V_0 \cos 2\pi t/T\), where \(V\) is the maximum tidal stream and \(T\) is the semi-diurnal tidal period of 12 hrs. 25 mins. The average rate of dissipation of energy over each square centimetre is therefore equal to the mean value of \(k\mu^2\) assuming \(2\pi T/\mu\).

Applying this to the case of the Irish Sea, taking \(V = 2\) knots, Mr. Taylor finds that the mean rate of dissipation of energy is \(k = 350,000\) ergs per sq. cm. per second. By an independent calculation of the rate at which energy flows into the Irish Sea, Mr. Taylor shows that it is possible to find the approximate value of \(k\). Taking the southern entrance to the Irish Sea between Arklow and Barley Island, from the known data of the depth of the channel, strength of the current, and range of tide in mid-channel, the mean rate at which energy is transmitted across this section is \(6.4 \times 10^9\) ergs per second. The flow through the North Channel is shown to be negligible compared with this value. In order to arrive at the loss of energy by frictional drag it is necessary to subtract the work done against the moon's attraction by the water. This is estimated by Mr. Taylor to be 110 ergs per sq. cm. per second. Taking the area of the Irish Sea to be \(3.4 \times 10^9\) sq. cm, the energy transmitted is 1640 ergs per sq. cm. per second, and subtracting the 110 ergs to the work done against the moon's attraction, we have 1530 ergs per sq. cm. per second.

Equating this to the above value obtained from the frictional resistance 550,000 \(k\), we have \(k = 0.0264\). This is in good agreement with the limiting values of \(k\) given by the curves of Fig. 12.

\[\text{(26) The Friction of the Wind on the Earth's Surface.} - \text{Assuming that the skin friction of the wind on unit area of the earth's surface can be expressed in the form } \mathcal{F} = BQ^2, \text{ where } Q, \text{ is the velocity of the wind near the surface of the ground, the value of } k \text{ has been calculated by Mr. G. I. Taylor}^2 \text{ from his theory of eddy motion and certain meteorological data obtained at Salisbury Plain.}

Referring to the sketch of this theory given in \(\text{§ (13)}\) above, it will be seen that if \(P, P_v\) and \(P_u\) are the components of the friction of the wind along axes parallel and perpendicular to straight isbars and \(x\) and \(y\) the components of the wind parallel to these axes, then

\[F_x = \int_0^\infty \mu \frac{dP_u}{dz} \, dz = \mu \left[ \frac{dP_x}{dz} \right]_{z=0},\]

and

\[F_y = \mu \left[ \frac{dP_y}{dz} \right]_{z=0}.\]

where \(\mu\) is the coefficient of eddy viscosity. The total skin friction is evidently

\[P = \sqrt{F_x^2 + F_y^2}.\]

Now from the equations of \(\text{§ (13)}\) follows that

\[\left[ \begin{array}{c} \frac{dP_x}{dz} \bigg|_{z=0} = 2 \tan \alpha \frac{\tan^2 \alpha}{1 + \tan^2 \alpha} Q_0 \frac{3 \pi + a}{H_1} \\ \frac{dP_y}{dz} \bigg|_{z=0} = 2 \tan^2 \alpha \frac{\tan^2 \alpha}{1 + \tan^2 \alpha} Q_0 \frac{3 \pi + a}{H_1} \end{array} \right];\]

and hence

\[P = 2\mu Q_0 \sin \frac{3 \pi + a}{H_1} \cdot \cdot \cdot \cdot \cdot \text{(3)}\]

so that, if, following the ordinary convention, we write \(P = \rho Q^2\) \(k\), we have

\[\rho Q^2 = \rho \frac{2\mu Q_0}{\sin \frac{3 \pi + a}{H_1}} Q_0 \cdot \cdot \cdot \cdot \cdot \text{(4)}\]

\(^1\) "Friction in the Irish Sea," Phil. Trans. Royal Society, cxxxv. 1.

where \( h \) is the variable distance between the surfaces and is a function of \( x \). Since the surfaces are nearly parallel, \( v \) will be small compared with \( u \) and the rate of variation of \( u \) in the direction of \( x \) will be small compared with its rate of variation in the direction of \( y \).

Accordingly equations (1) and (2) become

\[
\begin{align*}
\frac{\partial p}{\partial y} &= 0, \quad \text{(5)} \\
\frac{\partial p}{\partial x} &= \mu \frac{d^2 u}{d^2 x}, \quad \text{(6)}
\end{align*}
\]

From (5) it is seen that \( p \) is independent of \( y \), and (6) becomes

\[
\frac{\partial p}{\partial x} = \mu \frac{d^2 u}{d^2 x},
\]

which is then integrable, giving

\[
u = \frac{1}{2} \mu \gamma \left( y - h \right) + U \left( \frac{h - y}{h} \right). \quad \text{(7)}
\]

Now from (3)

\[
\int_{0}^{h} \frac{\partial p}{\partial x} \ dx = - \int_{0}^{h} \nu \ dx = 0,
\]

therefore, substituting the value of \( \partial u/\partial x \) from (7) and integrating, we have

\[
\begin{align*}
\frac{\partial p}{\partial x} &= \frac{\mu U \gamma}{\epsilon^2} \left( h - h_1 \right), \quad \text{(8)}
\end{align*}
\]

where \( h_1 \) is the value of \( h \) for which \( \partial p/\partial x = 0 \).

Let Fig. 36 represent a section through the shaft and journal, and let \( O \) be the centre of the journal of radius \( a \) and \( O' \) the centre of the bearing, \( a + b \) its radius, and let \( O' = c \eta \) where \( c < 1 \).

Then the value of \( h \) can be written \( h = \gamma (1 + c \cos \theta) \) where \( \theta \) is the angle \( PO'O' \).

Hence, writing \( x = ab \), \( h_1 = \gamma (1 + c \cos \theta) \), we have

\[
\begin{align*}
\frac{\partial p}{\partial x} &= \frac{\mu U \gamma \cos \theta}{\epsilon^2} \cdot \left( 1 + c \cos \theta \right),
\end{align*}
\]

from which

\[
p = \frac{C + \frac{\mu U \gamma}{\epsilon^2} \int \cos \theta \ d\theta}{(1 + \cos \theta)^2}
\]

Thus \( p \) can only have one value for any given value of \( \theta \), and therefore the coefficient of \( \tan^{-1} \left( \sqrt{1 - c} \left( 1 + \cos \theta \right) \right) \) in the above equation must be zero, i.e.

\[
3c \left( 2 + c \right) \cos \theta = 0, \quad \text{(11)}
\]

This equation determines the points at which \( (dp/d\theta) = 0 \), and substituting this value of \( \theta \) in equation (10), we have

\[
p = C \frac{\mu U \gamma \sin \theta (2 + c \cos \theta)}{(2 + c^2) \left( 1 + c \cos \theta \right)^{1/2} \left( 1 + c \cos \theta \right)^{1/2}}.
\]

It will be seen from this that the positions of maximum and minimum pressure are equidistant from the point of nearest approach, and the one value lies above the value of the pressure at that point by as much as the other value falls below it. The distribution of the pressure for values of \( C \) of \( 0.1, 3, \) and \( 5 \) is shown in Fig. 37. The total vertical force on the journal due to the pressure acts downwards through \( O \) and is given by

\[
R = \int_{0}^{2\pi} \sin \theta \ d\theta = \frac{2 \pi U \gamma}{\sqrt{(2 + c^2)(1 - c^2)}}.
\]

The total force due to the viscous drag on the surface of the journal must act through \( O' \) and is given by

\[
S = \int_{0}^{2\pi} \sin \theta \ d\theta.
\]

Again the couple exerted on the journal is

\[
M = \int_{0}^{2\pi} \sin \theta \ d\theta = \frac{2 \pi U \gamma}{\sqrt{(2 + c^2)(1 - c^2)}}.
\]

Now if \( f' \) be the viscous drag on the surface of the bearing

\[
f' = \frac{4 \pi U \gamma}{\sqrt{(2 + c^2)(1 - c^2)}}.
\]

Hence on the bearing the corresponding forces and couples are \( R' \) acting upwards through \( O' \) and equal to \( R \)

\[
S' = \frac{4 \pi U \gamma}{\sqrt{(2 + c^2)(1 - c^2)}}.
\]

Now \( S \) and \( S' \) are not equal and opposite, but being of a smaller order than \( R \) and \( R' \) may be neglected. In fact it has been shown by Sommerfeld that a closer approximation
would be as indicated by the curves in Fig. 33. In this case the position of nearest approach HG is vertically above the centre of the journal, the pressure of the film relative to the pressure at this position being positive on the one side and negative on the off side, and the distribution being such that the total vertical component is zero and the total horizontal component equal to the horizontal component of the friction.

On applying a vertical load it is essential for equilibrium that the positive vertical component of the oil pressure should exceed the negative component by the amount of the load imposed, and consequently the bearing lifts away into the position shown in Fig. 34, in which the resultant of the vertical pressure of the oil and the friction of the bearing surface exactly balances the load. As the load increases it appears from the theory that the position of nearest approach moves up to the left extremity of the bearing and that on further increasing the load it moves back again towards the central position. Further, when the load is in such a position that the least separating distance H O is almost half the difference in radii of bearing and journal the angular position of H O is about 45° to the off side of the centre line. At this position the pressure on the oil film is everywhere greater than at A and B, the extremities of the bearing and the effect of any additional increase in the load is to produce a negative pressure at A which in practice will produce rupture of the oil film.

It is fairly obvious, therefore, that this condition is the one which obtained in Mr. Tower's experiments at the instant when "seizing" occurred, and may be regarded as determining the maximum load on the bearing. It was possible, therefore, to obtain a check on the accuracy of the theory by calculating the distribution of pressure from the equations when the distance of nearest approach of the surfaces was half the difference of the radii, and comparing this theoretical distribution with the one actually observed by Mr. Tower. This comparison has been carried out in Fig. 35, the full curves indicating the theoretical distribution of pressure on an angle base and the crosses the observations. It will be seen that the agreement is very satisfactory.

The mathematical theory of friction under the conditions obtaining when plane or cylindrical surfaces supplied with a lubricant move relatively to each other has also been developed by Sommerfeld, Michell, and Harrison. As the treatment of the problem of the cylindrical bearing by Harrison is simpler than that of Osborne Reynolds, owing to the fact that he has assumed that the bearing is a complete cylinder instead of a half-cylinder and leads in the case of two dimensions to an exact solution, a brief account of the analysis is given here.\(^1\)

(iii) Harrison's Theory.—In forming the equations of motion of the film the effect of gravity and of the inertia of the fluid can be neglected compared with the internal stresses arising from the shearing of the liquid. Also, on account of the thinness of the film, its curvature can be neglected so that the same equations hold whether the surfaces are plane or cylindrical. In the equations \(x\) is measured along the moving surface in the direction of motion, \(y\) being normal to this surface. The motion is steady and assumed two-dimensional.

If \(u, v\) be the component velocities at any point in the liquid, \(p\) the pressure, the equations of motion are (see p. 315)

\[
\frac{\partial p}{\partial x} = \mu \frac{\partial^2 u}{\partial y^2}, \quad \frac{\partial p}{\partial y} = \mu \frac{\partial^2 v}{\partial x^2}
\]

where \(\mu\) is the coefficient of viscosity, and the equation of continuity is

\[
\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0.
\]

The boundary conditions are

\[
\begin{align*}
    u &= U, \quad v = 0, \quad \text{where } y = 0, \\
    u &= 0, \quad v = 0, \quad \text{where } y = h.
\end{align*}
\]

I'KHTION

...
would establish their identity. The inequality of \( M \) and \( M' \) is, however, an essential characteristic of the equality of the force systems \((R, M), (R', M')\), acting at 0 and \( M' \) at \( O' \). Taking different values of \( c \) the ratio of \( M \) to \( M' \) is

\[
\frac{c}{M/M'} = \frac{1 + 2c}{3ac}
\]

To the coefficient of friction for the journal is given by

\[
\lambda = \frac{M}{Kc} = \frac{1 + 2c}{3ac}
\]

and that for the bearing \( \lambda' \) by

\[
\lambda' = M' = \frac{1 - c}{3ac}
\]

An appreciation of these facts is of value in the practical determination of the coefficients of friction of bearings in laboratory experiments, for if, as is almost universally the practice, the friction on the bearing is determined it is evident that the actual coefficient of the journal is considerably greater than the value so determined unless the speed be sufficiently great to make \( c \) comparatively small.

The fact that the frictional resistance of a journal running at constant speed increases slightly as the load is increased may be illustrated by calculating the values of \( M \) and \( R \) from equations (13) and (15) for given values of \( c \) and assumed values of \( \mu \), \( U \), \( a \), and \( \eta \).

![Figure 38](image)

and plotting the results. This has been done in Fig. 38 for a bearing and journal in which

\[
U = 500 \text{ cm. per sec.,}
\]
\[
a = 2.5 \text{ cm.,}
\]
\[
\eta = 0.005 \text{ cm.,}
\]
\[
\mu = 1
\]

the calculated values of \( R \) and \( M \) being as follows:

<table>
<thead>
<tr>
<th>( c )</th>
<th>( R ) in Grammes.</th>
<th>( M ) in Grammes cm.</th>
</tr>
</thead>
<tbody>
<tr>
<td>-1</td>
<td>240,000</td>
<td>4084</td>
</tr>

<td>1831</td>
</tr>
<tr>
<td>5</td>
<td>1,200,000</td>
<td>2436</td>
</tr>
</tbody>
</table>

It will be seen that by increasing the load in the ratio of 5 to 1 the friction is increased by 67 per cent.

The variation in the amount of the frictional resistance as the speed is increased, the load remaining constant, may be shown by calculating the values of \( U \) and \( M \) from equations (13) and (15) for different values of \( c \), \( R \) being constant.

This has been done for the same bearing, journal, and lubricant as in the previous example, taking the value of \( R \) as 1,232,560 grammes when \( c = 0 \).

The calculated values of \( U \) and \( M \) are as follows:

<table>
<thead>
<tr>
<th>( c )</th>
<th>( U ) Cal. p.s.</th>
<th>( M ) Grammes cm.</th>
</tr>
</thead>
<tbody>
<tr>
<td>-5</td>
<td>0.5</td>

<td>16.73</td>
</tr>
</tbody>
</table>

The results are shown in Fig. 39, in which the ordinates are the values of \( M \) and the

absissae those of \( U \). It will be seen that at the low speeds an increase in the speed of about 30 per cent only results in an increase in the frictional resistance of about 8 per cent, but at the high speeds the friction is practically proportional to the speed.

It should be noted that the above deductions from Harrison's theory—the ratio of the couple on the journal to that on the bearing and the variations of friction with load and speed—are based on the assumption of a film of lubricant which is continuous round the journal and in which the pressure distribution is symmetrical about a horizontal section through the axis, as in Fig. 37. No experimental investigation of the pressure distribution in a lubricated bush appears to have been made, but from some preliminary observations at the National Physical Laboratory it would appear that such a symmetrical distribution is not commonly obtained in practice.

§ (29) Functions. Resistance of Flat Inclined Surfaces. (1) Michell's Theory. The hydrodynamical theory of the pressure distribution between two flat inclined surfaces separated by a film of fluid has been worked out by Michell, who has obtained a complete

1 Zeitschrift für Mathematik, 1005, III
Australia in 1805, and since that time the development of this type has been very rapid. Fig. 45 shows a bearing on this principle designed by Mr. Newbiggin for Messrs. Bellis & Morris of Birmingham for a steam turbine. In this A is the collar on the shaft, B is the segmented rubbing blocks, the backs of which are cut out to allow of them tipping through the necessary angle to the plane of rotation. C are spacing blocks between which the loose rubbing blocks are fitted. D is the case holding the spacing and rubbing blocks together. F is a washer, same on one face and flat on the other, to provide means of automatic adjustment. The oil is supplied through a hole in the centre of the shaft S. This bearing was tested under a total load of 1500 lbs. or 300 lbs. per sq. inch at a speed of 1750 revolutions per minute, under which conditions it ran continuously at a temperature of 124°F. Owing to the smallness of the angle of inclination of the surfaces it is not practicable to have them fixed, and the blocks are pivoted about an axis passing through the line of action of the resultant of the oil pressure and the friction. In this way the block automatically sets itself to the correct inclination. Designed in this way thrust-bearing have been constructed which have run continuously with a pressure as high as 3000 lbs. per square inch.

IV. THE FRICTIONAL RESISTANCE OF SOLID SURFACES SEPARATED, OR PARTIALLY SEPARATED, BY A FILM OF FLUID OF SMALL DIMENSIONS LACKS A POSITIVE RESISTANCE DUE TO THE SHEARING STRESS IN THE FLUID ALONE

§ (39) Oiliness. — In the case of the frictional resistance of surfaces separated by a film of fluid whose motion can be predicted from the equations of hydrodynamics, such as those discussed earlier in this article, it is, of course, obvious that the resistance is entirely independent of the nature of the surfaces and dependent only on the characteristics of the fluid, so that it may be assumed that, in the case of two bearings and journals of identical dimensions and speed and loaded in such a manner that the relative position of journal and bearing is the same for each, but supplied with different lubricants, the frictional resistances are proportional to the coefficients of viscosity of the two lubricants used. It has long been known, however, by practical engineers that trouble in running machinery caused by hot bearings can be cured by the use of certain oils whose viscosity was of the same order as that of the oil used in the hot bearing. Thus in the case of the heating up of the fluid plane of gas-engines lubricated by mineral oil it is common practice to substitute center oil for the mineral oil, with the result that the friction diminishes to its normal value and smooth running results. Now the value of μ for center oil does not differ appreciably from that of a good lubricating mineral oil, so it is evident that the former possesses some lubricating property apart from its viscosity. Although considerable attention has been devoted to the study of this property of good lubricants, no definite rotation has yet been found between it and the other physical properties of the oil, and the property itself is somewhat vaguely referred to as "oiliness." There seems, however, to be no doubt that the determining factor of oiliness is the chemical composition of the lubricant and that those oils which contain a large proportion of unsaturated hydrocarbons are the best lubricants. An explanation of the relative superiority as regards lubricating value of animal and vegetable oils over mineral oils is suggested by Langmuir's theory of adsorption. According to this theory, the fact that animal and vegetable oils spread upon water whereas mineral oils do not is due to the presence of an active group in the molecule in the former case and its absence in the latter. The soluble glycerine ester end of the red-like molecule tends to dissolve in the water, but the insoluble hydrocarbon end refuses to do so, with the result that the molecule stands on end and the surface of the water is covered with a layer of closely packed molecules of the animal or vegetable oil. On the other hand, the mineral oils with hydrocarbon groups at each end of the molecule are inert, and spreading does not take place. Similarly, when a liquid whose molecules contain active groups is in contact with a solid surface adsorption takes place and the
any point \( x, \alpha, \beta, \) as precisely as in equations on p. 377, is given by

\[
f_\alpha = -\mu \left( \frac{\partial p}{\partial \alpha} \right) \frac{\partial p}{\partial \alpha} = -\mu \frac{U}{h} \frac{\partial p}{\partial z}.
\]  

where \( U \) is the velocity of the fluid in the direction of \( x \) at \( x, y, z \).

The resistance of the whole block is therefore given by

\[
\int_0^b \int_0^c \left( \frac{U}{h} \frac{\partial p}{\partial z} \right) dz dx.
\]

\[
= x \int_0^b \int_0^c \left( \frac{U}{h} \frac{\partial p}{\partial z} \right) dz dx.
\]

\[
= \frac{\pi U}{2} \log \frac{b}{c} + \frac{c}{2} P.
\]

\[\text{(11)}\]

(b) The Results of the Application of the Theory to Special Cases. Case I. Square Block—length of side \( r = b = 2a \).—The distribution of pressure over the block is shown in Fig. 41, in which the lines of equal values of \( p U \), i.e. equal values of \( \frac{pU}{\rho} \), are shown. For tables of the values of the Bessel functions required and the method of obtaining the values of the coefficients, reference may be made to the original paper. The mean pressure is found by arithmetical summation to be \( \bar{p} = (1/\pi) \int_0^\pi p \sin \theta \cos \theta d\theta \), and the position of the resultant pressure is about \( -42\pi \) from the rear end of the block. The nominal coefficient of friction is

\[
\mu = \frac{F}{D} = 10.836a.
\]

Case II. Slide Block of Width equal to one-third of its Length, \( h = 2a \), as before.—The distribution of pressure is shown in Fig. 42, the mean pressure is given by

\[
\bar{p} = \frac{1}{3\pi} \int_0^\pi p \sin \theta \cos \theta d\theta = -0.0155 \frac{U}{c},
\]

and the position of the resultant pressure is at \( 39 \) of the length of the block from the rear end.

The coefficient of friction is 1436, or thirteen times greater than in the case of the square block.

Case III. Slide Block of Infinite Width.—Assuming \( h = 2a \) as before, the mean pressure is \( \bar{p} = -0.0090 \left( \frac{U}{c} \right)^2 \), the resultant pressure acts at \( 1.433 \) of the length of the block from its rear end, and the coefficient of friction is \( \pi \) or less than half of that of the square block.

The distribution of pressure along the middle line \( z = x/2 \) in this case compared with that for the square and rectangular blocks is shown in Fig. 43, in which the influence of the transverse flow in reducing the pressure at the side is clearly brought out.

The practical application of the essential conditions to secure perfect lubrication between two flat surfaces, indicated by the theory, has led to very great improvements in the design of the thrust blocks of marine engines. Previously collar-thrust bearings of the type shown in Fig. 44 were in use. These consisted of collars forming part of the shaft in contact with thrust washers sliding in grooves in the thrust block and transmitting the thrust of the propeller bolts. Oil was admitted to the surfaces in contact through radial grooves cut in the thrust washers, but as the two surfaces were elliptical it is evident that no separating oil film could be formed, with the result that the maximum pressure which could be used without seizing was of the order of 60 lbs. per sq. inch. The size and cost of the thrust blocks of large marine engines were therefore very great. The first thrust bearing in which the theoretical condition of an inclination of the surfaces was fulfilled was made by Mr. A. G. M. Michell in
molecules orient themselves into the surface layer of the solid in the same manner. We may therefore regard the lubrication of surfaces in apparent contact as being in the extreme case a condition in which the surfaces are separated by a layer of oil one molecule thick, resembling a piece of velvet firmly glued to the metal with the pile outward. Two such velvet-like surfaces will presumably be able to slide over each other with little friction, and that lubricant will be the most efficient in which the sliding action over the metallic surface is the most complete. It is evident that the action here presumed will depend on the chemical composition of the surface of the bearing, and this stands as explanation of the well-known fact that in cases of lubrication in which, owing to the circumstances of the motion and bearing, perfect film lubrication cannot take place, the frictional resistance depends on the nature of the metallic surface, with the result that “lubrication metal,” as the one called, are much used. Mr. Archbatt has recently found that under the same conditions of speed, and nature of lubricant the lining of a bronze bearing with white metal enabled double the load to be carried.

(6) Relations between Lubricant and Surface. By Mr. B. P. Baines. The lubrication of surfaces is a condition mentioned above and the determination of the coefficient of friction between surfaces of different metals in contact when lubricated with various oils have been investigated by Mr. B. P. Baines, who has constructed a special machine for the purpose. In this machine (Fig. 49) the two steel pucks each 2 inch in diameter, are firmly placed in a circle of 7 cm. diameter test on the flat surfaces of a disc of metal which can be finely rotated. The pucks are moved by an upper disc which can be held vertically or horizontally and which moves in a spindle to which a spiral spring and recording index are attached. When the lower disc is rotated the upper disc is carried with it by means of the frictional resistance between the surfaces of the pucks and the lower disc, the index recording the value of the torque, until slipping occurs. A pad and ledger are attached to the pucks to prevent the index from moving back along the axis when slipping takes place. The movable disc on which the pucks rest lies in a wooden dish which can be filled with oil. The mechanical details of the machine will be found from Fig. 46. In order to obtain clean surfaces of the disc and pucks these were ground under water with abrasive paper; then polished with fine wet and dry chalk, rubbed well in water, then put in a bath to remove any trace of oil, dried with clean blotting paper, and finally heated to get rid of all traces of moisture. As soon as the surface

\[ \text{Equation missing}\]

was dry it was wetted with the liquid to be tested, placed in the machine, and the torque between the two discs determined at the various speeds of rotation.

The frictional effect of the metal of the surface of the disc and the metal of the pucks employed the frictional effect of the metal made by Mr. P. Baines is to be replaced. The

The results obtained by Mr. Baines for various lubricants and the results for the same lubricants were obtained by the present author and are given in Table 1. From the results it will be seen that the coefficient of friction for oil A is less, higher than for oil B and C, the slip for oil C being greater than for oil B. The amount of the difference is due to the nature of the oil itself, the lubricating performance of the oil varying from 0.15 per cent. for oil A to 0.20 per cent. for oil C, the slip being higher for oil A. It is evident from the results that the material used for the bearings, the bush, and the solid metal itself was found to be the best lubricant.

The present lubricants when used by Mr. Baines differ from the present-day lubricants employed by engineers in the past.
FRICION

383

"Oiliness" appears to be an effect produced by the lubricant upon the metallic surfaces with which it is in contact rather than a property depending on any particular physical property of the lubricant. It would appear as a result of abrasion forming a paste of metal plus oil between surfaces covered by oil layers one molecule thick. - A

* A = animal oil; V = vegetable oil; M = mineral oil; B = blended oil.

The uncontacted molecules of the lubricant enter into a firm physical-chemical union with the metallic surfaces, thus forming a friction surface which is a compound of oil and metal. This solid surface would also appear in the case of metallic surfaces to be much more than one molecule thick, the oil either penetrating some little distance into the metal and altering its physical properties

FIG. 47.

worm-gear when using different kinds of oils, and were carried out for the Lubricants and Lubrication Inquiries Committee of the Department of Scientific and Industrial Research. The testing machine was specially designed by Mr. E. W. Lanchester for the accurate measurement of the efficiency of power transmission through a worm-gear. A sketch of the machine is given in Fig. 47 and an enlarged view showing a section of the gear-box and the oil circu-
lating system in Fig. 48. It will be seen from
Fig. 47 that the gear-box is supported in a
cribble A in such a manner that it has freedom
of motion through a small angle about two
axes at right angles. The worm is driven by
the shaft B through the intermediate shaft C,
the latter being provided with universal
 couplings at each end. In the same manner
the worm-wheel shaft is connected to the
bevel box E, through the shaft D, and the
universal couplings F, E. The load is supported
by a bracket K fixed to the arm O, the axis
of this arm being parallel to and in the same
vertical plane as the worm-shaft axis. The
load is not fixed directly to the bracket but
is carried by a slider, and by means of a screw
and nut device the distance of the load from
the axis of the arm can be varied. The
 bracket is permanently fixed to the arm and
thus the moment of the load about the worm-
wheel axis is equal to the load multiplied by
the length of the arm and is always the same
for the same load. The moment about the
worm-shaft, however, can be adjusted by
means of the screw-gear, there being a scale
showing the distance of the
's of the
if the

d the distance of the load to obtain a
of the gear-box is the efficiency of t
The drive is taken through the bevel
the belt pulley M, the latter being of
diameter that it tends to drive the
keyed to the driving shaft B at from
5 per cent higher speed than it is a
making. In this way, by the friction
 ping of the belt over the surface of the
keyed to the shaft B, all the power
milled through the gear, with the exi
of that lost in friction of the bevel-shaft-journals, is returned to the driving.
The system constitutes, therefore, a
 circuit, and all that is necessary to be a
from outside sources is the total loss due to the friction of the whole machine. This loss is supplied by a belt drive to the cone pulley P from a 15-h.p. petrol motor. It is arranged that the tension in the belt connecting the pulleys M and N can be adjusted over a wide range, an increase in the belt tension causing an increase in the pressure between the teeth of the worm and worm-wheel, and therefore an increase in the torque. In the machine described the pressure between the teeth could be increased to a value corresponding with a transmission of 100 h.p.

Fig. 48 shows in detail the method of supporting the gear-box. It is held by means of the ball-bearing CC in the cradle A, which can itself rotate through a small angle by rolling in the ball-bearing rollers B and B.

The lubricant contained in the tank shown in Fig. 48 is fed into the top of the gear-box by means of a rotary pump, and leaves by means of the pipe K, the hole in the side of the box being about on a level with the top of the worm. The temperature of the oil entering and leaving the gear is taken by thermocouples. It was estimated that in the experiments the absolute accuracy of the efficiency obtained was within 0.2 and 0.3 per cent of the true value, and the agreement of the readings was within 0.1 per cent. A difference corresponding to 0.1 per cent in the efficiency could easily be detected when the apparatus was running steadily. The gears tested were of the Hinchley type, cut by the Daimler Company on Mr. Lancaster's principle, by means of which a high efficiency of transmission is secured even under extremely heavy loading of the lubricated surfaces. In the tests to be described the mean pressure on the surface ranged from 1/2 to 2 tons per square inch, and efficiencies of 97 per cent were obtained.

A brief description of the results obtained with various lubricants may be given.

In carrying out the tests it was found that starting with the lubricant at the normal temperature of the room the heat developed in friction at the surface of the worm and wheel was such that the temperature of the oil in the receiver gradually increased, thus enabling a consecutive series of observations to be carried out at gradually reduced values of the viscosity.

(iii) Experimental Results. — A complete series of efficiency tests at temperatures of the lubricant ranging from 15° C. to 75° C. were carried out on the following oils:

(iii) The Critical Temperature. — In the case of all the mineral oils tested it was found that when a certain temperature of the oil had been reached, called the "critical temperature," the running of the decidedly unsteady, and a in the case of all oils of the same type was observed. Exp critical temperature was considered that the oil carried further without it, the case of animal and ...
critical stage was reached at temperatures below 75° C., beyond which the tests were not carried.

(iv.) Conclusions.—The general nature of the results at a mean pressure on the teeth of 15 ton per square inch are indicated by the curves in Fig. 40, of which the ordinates are the values of the efficiency of transmission and the abscissae the values of the temperature of the lubricant.

It will be seen that at atmospheric temperature the efficiencies of the four fixed oils are appreciably higher than those of the mineral oils, but that in all cases the efficiency is remarkably high, varying from 93.5 for the FFF Cylinder to 95.5 for the fixed oils. When the temperature exceeds 30° the extreme range in the efficiency is not so large as at 20°, and the relative performance is maintained up to about 47° C., at which the critical point of the Bayonne oil is reached and its efficiency falls rapidly. The critical point of the Victory Red oil is not so well defined, but would appear to be approximately 50° C. The performance of the FFF Cylinder, however, remains remarkably constant up to a temperature of 17° C., when a very rapid break in the behaviour of the oil was noted, and the efficiency fell, as in the case of the other mineral oils. The behaviour of the Sperm oil was somewhat abnormal, as the efficiency appeared to form continuously from 30° to 60° and then remained steady. There was, however, no sign of a critical point having been reached. There can be no doubt that the relative superiority of the fixed oils is due to the absence, within the range of temperature obtained, of a critical point. The fact that the critical points of two of the mineral oils were reached at a temperature of 50° C. would have an important bearing on their practical value as lubricants, since such temperatures are not uncommon in internal combustion engines and turbine lubrication.

In Fig. 60 are exhibited the results of the same series of tests plotted on a base of absolute viscosity of the lubricant instead of temperature. It will be seen that throughout there is no indication that the frictional resistance of the gears is even approximately proportional to the viscosity of the lubricant employed, as would be the case if the surfaces were separated by a film of oil of measurable thickness. This conclusion is strikingly verified in the comparison of the results for Castor and Trotter oils. At 40° C. the viscosity of Castor oil is approximately six times that of Trotter, but in the tests at this temperature the frictional resistances were approximately the same. As regards the effect of pressure, it was found that there was an appreciable increase (2 per cent) in efficiency obtained by raising the pressure from 15 to 2-0 tons per square inch, and further there was an increase of 1 per cent in the efficiency by raising the speed of the worm-shaft from 500 to 1500 r.p.m.

(v.) Effects of Mixture.—As practical experience showed that the lubricating value of a mineral oil could be increased by adding a certain proportion of animal or vegetable oil to it, some experiments on various mixtures were made. It was found that the addition of Rape oil in any proportion to the mineral oils did not appear to increase the efficiency very appreciably—an increase of 0.2 per cent was noted—but the critical temperature of the oil to which the addition of Rape was made was raised considerably. This effect of raising the critical temperature could be obtained with the addition of as small a quantity of Rape as 2.5 per cent, and increasing this amount up to 25 per cent did not appear to make any very marked improvement as regards changing the critical point. The general effect of varying the percentage of Rape oil added to a mineral oil is shown in Fig. 51. Experiments were also made on the effect of adding Castor oil in various proportions to a mineral oil, and similar results to those observed in the case of Rape were obtained. To determine whether the beneficial effect of adding the fixed oil to the mineral oil was due to the fatty acids
contained in the fixed oil, the following comparative tests were made:

1. Tests on Bayonne oil alone.
2. Tests on Bayonne oil with 10 per cent of acid Rape added.
3. Tests on Bayonne oil to which 10 per cent of Rape oil, from which the fatty acids had been removed, was added.
4. Tests on Bayonne oil to which 1-0 per cent of Rape oil fatty acids had been added.

The results are shown in Fig. 52. It will be seen that the effect of adding 1 per cent of fatty acids to the Bayonne is to produce a marked improvement in the efficiency and to raise the critical point from 47° C. to 57° C. The addition of the Rape oil from which the fatty acids had been extracted produced, on the other hand, practically no improvement. The general results of the tests may therefore be taken as confirmatory of the hypothesis that the fatty acids in the fixed oils are the main factors in the relatively greater lubricating efficiency of these oils.

A series of experiments was also undertaken to determine the effect of adding de-oiled graphite to the oils. This is a special preparation of graphite in a finely divided state which when mixed with oils forms a colloidal mixture called "Oildag," from which the graphite cannot be separated by mechanical means. The general effects of adding Oildag to the lubricants was as follows:

1. Oildag.—General lubricating efficiency unaffected by the addition.
2. Caster.—A small rise (about 0-5 per cent) in the efficiency due to the addition was observed.
3. Bayonne.—The temperature efficiency curve did not show the characteristic critical point, the efficiency falling gradually with rise of temperature up to 80° C.
4. FPF Cylinder.—A small increase of efficiency (0-2 to 0-4 per cent) due to the addition, and a rise of the critical point from 72° C. to 80° C. was noted.
5. Victory Red.—The critical period was smoothed out and a rise in the efficiency of about 0-5 per cent was noted.

The general results showed that the addition of the Oildag was to reduce appreciably the differences between the mineral oils and to bring their lubricating efficiencies to nearly the same value.

Oildag appears, therefore, to have the effect of rendering an inferior mineral oil as good a lubricant as a superior one in that it not only raises the lubricating value of an inferior oil, but considerably reduces the rate of fall of efficiency which usually occurs at temperatures above the critical value.

(vi.) Tests on the Addition of Flaked Graphite to the Lubricants.—The results of the use in
the testing gear of a mechanical mixture of oil and graphite in a finely divided state was also tried. In these experiments the graphite lubricating properties, but it is not certain that this would be the case with all oils.

\[ V = \text{The Friction of Dry Solid Surfaces} \]

(31) LAWS OF FRICTION. — As would be expected from the imperfect knowledge of the molecular and molar actions which take place at the surfaces of separation of solid bodies in contact, the nature of the surface action is still obscure and, in consequence, the so-called laws of solid friction are largely empirical. Further, it is now recognised that these laws are only rough approximations owing to the fact that the experiments upon the results of which they are based were, for the most part, made on surfaces which were not clean and were usually contaminated by the presence of some fluid moisture, the presence of which materially affected the frictional resistance.

In the case of two solid bodies in contact over a surface the component of any external force tending to cause the relative motion of the two bodies by sliding over this surface is exactly balanced by the frictional resistance between the surfaces up to a certain limiting value of the external force, and if this value is exceeded, sliding of the bodies takes place.

The fundamental law of solid friction is that this limiting value of the frictional resistance is a definite fraction of the normal force with
which the surfaces in contact are pressed together.

**Coefficient of Friction: Angle of Repose.**

The value of this friction is called the coefficient of friction $f$, and depends on the nature of the surfaces. For example, in Fig. 53 let $XY$ be the trace of the surface of contact, and let $P$, inclined at an angle $\phi$ to the normal, be the resultant force exerted on one body by the other body.

Then the force with which the bodies are pressed together is $P \cos \phi$ and the lateral force tending to make them slide over each other is $P \sin \phi$. Now by the law of solid friction $P \sin \phi$ cannot exceed $P \cos \phi$ without sliding taking place, and therefore at the instant of sliding

$$P \sin \phi = fP \cos \phi$$

or

$$f = \tan \phi.$$  

It follows, therefore, that the greatest angle of obliquity of the resultant pressure to the normal to the surfaces is the angle whose tangent is the coefficient of friction. This angle is called the angle of repose, and is an essential condition for the stability of the structure, for the stability of the structure is that the obliquity of the pressure should at no joint exceed the angle of repose for the materials.

As an illustration of the application of the data of Table I, the stability of the buttresses in Fig. 54 may be calculated.

This is supposed to be made of strong brickwork, weighing 112 lbs. per cubic foot of the dimensions given in the cross-section, and of a uniform width of 5 feet. The buttresses have to sustain two inclined thrusts applied to the points indicated, the upper one being the thrust of a roof principal which is 5 tons, inclined at an angle of $30^\circ$ to the horizontal, and the lower one the thrust of an arch which is 8 tons, inclined at an angle of $15^\circ$ to the horizontal. It is evident that the joints which are most liable to slide are (11), where the thrust of the roof is applied, and the joint immediately below the point of application of the arch-thrust which is at (11). If these joints are secure the stability of the others need not be investigated. (Considering the joint (11), the lateral force tending to cause sliding is $5 \cos 30^\circ = 4.33$ tons. The weight of the buttress above GIL is 21.6 tons, which, added to the vertical component of the thrust, gives a total normal pressure on the joint of 24.4 tons. The maximum resistance to sliding may be calculated from the value of $f$ for brickwork, which from the Table in § (32) is seen to be 0.6, and is therefore 14.4 tons, or more than three times the actual lateral force. The joint is therefore safe.

Again, taking the joint EF, the total lateral force on the buttress above EF is
FRICITION

The frictional stability of earth is by the granular planes to exerted to the body surface, sliding of the excavation gives an angle, or sliding of the prism parts of the earth, weight of the prism, the prism parts are of the joint, or of the earth, which, by direct contact, may be balanced. The relation between them may therefore be obtained from the stress ellipse of a body subject to pressures parallel to one plane, the equation of which is 

\[ \tan \theta = \frac{a+b}{2} - \frac{ab}{3} \] 

where \( P \) is the stress on a plane whose normal is inclined to the axis of \( y \) at an angle \( \alpha \), and \( a \) and \( b \) are the maximum and minimum stresses. Thus, in Fig. 56, let \( OA = a \), \( OB = b \), and let \( zz \) be a plane whose normal makes an angle \( \theta \) with \( OM \), which represents the stress on \( zz \). The angle therefore represents the obliquity of the stress on \( zz \). Also, if \( P \) is the middle point,

\[ PQ = a - b, \quad RP = RQ = RM = \frac{P}{2} \]

and evidently the angle \( \theta \) is a maximum when \( RM \) is perpendicular to \( OM \) and \( \theta \).

Maximum angle of obliquity: \[ \sin \theta = \frac{a - b}{c} \]

and in that case \( OM = (a+b)/2 - (a-b)/2 \) or stress on \( zz = \sqrt{ab} \).

Again, for any value of the obliquity \( \theta \), we have, if \( OM = p \),

\[ \left( \frac{a-b}{2} \right)^2 = \left( \frac{a+b}{2} \right)^2 + \rho^2 - \frac{2}{3} \left( a+b \right) \rho \cos \theta \]

or

\[ \rho = 2 \left( a+b \right) \cos \theta \]

which gives the relation between the maximum and minimum stresses and the stress by the plane of the friction which it acts to. Now in the case of a mass of earth whose upper surface is either horizontal or inclined to the horizontal at a definite angle, it is clear that on any plane parallel to the surface, and whose depth below the surface is small compared with the length dimensions of the surface, the pressure is vertical and of a uniform intensity equal to the weight of the vertical prism divided by its unit area of the given plane.

Further, it follows that the stress on a vertical plane parallel to the horizontal of the first plane must be in a direction parallel to this plane, for considering equilibrium of a small prism ABCD (Fig. 50) whose centre is at O and whose faces are parallel to XOY and YOX, it is evident that the forces exerted by the other parts of the mass on the faces CD and AD are directly opposed and that they are independent of each other. The forces on AC and BD are therefore independently balanced, which cannot be the case when their direction is parallel to YOY. Stresses obtained in this manner are said to be correct stresses, and it is evident that their obliquity to the plane on which they act are the maximum.

If, therefore, we consider in Fig. 56 an external stress \( p' \) which is conjugate to \( p \), i.e., \( p' \) to have

\[ a + b = \frac{p + p'}{2} \quad \text{and} \quad a - b = \frac{p - p'}{2} \]

\[ \rho = \sqrt{\left( \frac{p + p'}{2} \right)^2 - 2 \cos \theta} \]
If \( \phi \) be the maximum obliquity, it follows that

\[
\sin \phi = \frac{a - b}{a + b}.
\]

\[
\left( \frac{p + p'}{2} \right)^2 \frac{\cos^2 \theta}{4p'} = \frac{\cos^2 \theta}{\cos^2 \phi}
\]

where \( p \) and \( p' \) are the roots of the quadratic

\[
P^2 - 2\frac{p + p'}{2} \cos \theta + \frac{\cos^2 \theta}{\cos^2 \phi} = 0.
\]

Applying this condition to the equilibrium of masses of earth in which one conjugate plane is a plane parallel to the surface of the ground and at a depth \( h \) below it, it is evident that the pressure per unit area of this plane is \( \cos \theta \), where \( \cos \theta \) is the weight per cubic foot of the earth and \( \theta \) is the inclination of the surface to the horizontal. The pressure on any other conjugate plane, which is vertical, as we have seen, parallel to the surface, \( \theta \) as regards its magnitude may be either a greater or the smaller of the two conjugate pressures; i.e., calling this conjugate pressure \( p \), the value of \( p \) may be either

\[
\frac{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}}
\]

or

\[
\frac{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}}.
\]

To find which value to take in any special case, recourse is had to a statistical principle known as Moseley’s Principle of Least Resistance, which is stated as follows. If the forces which balance each other in or upon a given object or structure be distinguished into two stems called respectively active and passive, which stand to each other in the relation of use and effect, then will the passive forces \( \phi \) the least which are capable of balancing the active forces consistently with the physical condition of the body or structure.

This proposition may be regarded as self-evident, since the passive forces being caused by the application of the active forces to the body or structure will not increase after the active forces have been balanced by them, and will therefore not increase beyond the least amount capable of balancing the active forces.

In a mass of earth loaded with its own weight the gravity of the mass is evidently an active force and the lateral pressure the passive force, and, therefore, the latter will owe the least value which is consistent with the conditions of stability. In the case of a footing, of a bank of earth with a plane surface, the pressure parallel to the deepest declivity on a vertical plane at a point distant \( h \) below the surface is

\[
\frac{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}}
\]

or, if the ground surface be horizontal,

\[
\frac{1 - \sin \phi}{1 + \sin \phi}.
\]

To find the resultant pressure against a vertical plane of depth \( h \) below the surface it is evident that, since the pressure is directly proportional to the depth, we may apply the ordinary rules of hydrostatics, from which the total depth from the surface and the resultant force is

\[
\frac{hW^2}{2} \cdot \frac{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}}
\]

§ (34) Case of the Supporting Power of Earth Footings. (I) Theory.—In the case treated above the conjugate pressure was caused solely by the vertical pressure due to the weight of earth above the point considered, and its value was therefore the smaller of the two conjugate pressures.

It is evident, however, that this conjugate pressure may be increased beyond this least amount by the application of the pressure of an external body—for example, the weight of a building founded on the earth. In this case the conjugate pressure will be the least which is consistent with the vertical pressure due to the weight of the building, and if that conjugate pressure does not exceed the greatest conjugate pressure consistent with the weight of the earth above the stratum on which the building rests, the mass of earth will be stable. The most important case in practice is when the surface of the ground is horizontal.

Thus, in Fig. 27, let \( p \) be the intensity of the pressure on a horizontal stratum due to the weight of the building. Then the horizontal conjugate pressure \( p' \), being the passive force, is given by

\[
p' = p \frac{1 - \sin \phi}{1 + \sin \phi}.
\]

The effect of \( p' \) is to cause an upward thrust on the earth immediately above the footings of the foundations, and calling this \( p'' \), then since \( p'' \) is also a passive force,

\[
p'' = p \frac{1 - \sin \phi}{1 + \sin \phi}.
\]

Now \( p = w h \), where \( w \) is the weight per cubic foot of the earth and \( h \) is the depth of the
foundation below the surface of the ground, and therefore

\[ p = \rho' \left( \frac{1 + \sin \phi}{1 - \sin \phi} \right)^2 = \omega h \left( \frac{1 + \sin \phi}{1 - \sin \phi} \right)^2. \]

It is evident that, if \( k \) has a less value than that given by this equation, there will be a tendency for the building to sink into the ground by forcing the earth upwards.

\( k \), therefore, is a minimum value to the depth of the foundations.

Again, if the depth is such that there is a tendency for the earth pressure to overcome the pressure due to the weight of masonry, as in the case of the floor of a dock before the water is admitted, then \( p' \) is the active force, and

\[ p' = \rho' \left( \frac{1 - \sin \phi}{1 + \sin \phi} \right)^2 = \omega h \left( \frac{1 - \sin \phi}{1 + \sin \phi} \right)^2. \]

The value of \( k \) determined from this relation gives a maximum which cannot be exceeded without danger of the masonry being forced upwards.

In applying this formula it must be remembered that by hypothesis the lateral extent of the mass of earth is large compared with the depth. When this is not the case, as in the region at the back of a retaining wall, the frictional resistance of the wall will affect the pressure distribution. It has been shown by Bousmeure \( \frac{1}{2} \) that at a distance \( x \) from the face of the retaining wall, if \( \theta \) be the angle of friction between wall and earth, and \( a^2 = 1 - \sin \phi / 1 + \sin \phi \), then for \( x < a \sin \phi / 2 \) the

\[ \text{Horizontal pressure} = \omega h/2 \left( \frac{1 + a \tan \theta}{1 + \sin \phi} \right)^2 \]

\[ \text{Vertical pressure} = \omega h/2 \left( \frac{1 + a \tan \theta}{1 + \sin \phi} \right)^2 \]

The ratio of the pressures is \( a^2 \) as in Rankine's theory. When \( x = 0 \) the horizontal and vertical pressures become \( \omega h / 2 (1 + a \tan \theta) \), \( \omega h / 2 (1 + a \tan \theta) \), and the tangential force on the face is evidently \( \omega h \tan \phi / 2 (1 + a \tan \theta) \).

(6) Experimental Verification.—The limits of accuracy in practice of the Rankine formula has been the subject of several very careful experimental investigations, and it has been found that provided the material is perfectly free from moisture the accuracy is remarkably high. Thus in some experiments by Wilson \( \frac{1}{2} \) on dry sand, the following results were obtained from direct observations of the ratio of the pressures, and by calculation of the ratio from the observed angles of repose of the sand.

### Table II

<td>0.320</td>
</tr>
<tr>
<td>By experimental measurement of the pressures</td>
<td>0.330</td>
<td>0.305</td>
<td>0.310</td>
</tr>
</tbody>
</table>

In these experiments the values of the angle of repose were obtained in two ways, one by placing the sand in a hop and subjecting it to vibrations until the surface had taken up a definite shape, and the other by placing the sand in a box with a sliding end which was opened gently after tapping. The extreme variation in the value of the observed angle of repose from these methods was from 30° to 32°.5°.

The pressures were obtained by placing the sand in a cast-iron cylinder 14 inches in diameter, 14 inches deep, provided with movable pistons at the top and bottom ends, the pistons being compressed between the platens of a 500-ton testing machine. In this way pressure equal to that due to a depth of 131 feet was obtained. The instrument used for measuring the pressure consisted of two steel discs of 3 inches diameter, separated by a ring, and containing mercury, the displacement of which due to the pressure was noted. By placing this alternately parallel to, and at right angles to, the direction in which the external pressure was applied, it was possible to determine the ratio of the two externally applied pressures, which gave the same displacement of the mercury and, therefore, the same pressure on the gauge. From the fact that the relation between the load and gauge indications for any position was a linear one, it followed that the ratio of the two loads was equal to the ratio of the horizontal and vertical pressures for the same load.

(35) Effect of Moisture on the Stability of Earth.—It is well known that the effect of moisture is to increase the cohesion and hence the stability of earth and sand. This is due to the surface tension of the film of water separating the grains, the amount of the traction depending on the amount of moisture. It was found by Wilson that, commencing with sand initially dry, the force between the grains increased with the percentage moisture up to a certain point and then decreased, but as long as the interstices were not entirely filled with water there was still some attractive force, and hence the ratio of horizontal to vertical pressure should be less than that for dry sand. On carrying out a series of experiments on sand containing varying percentages of moisture in the appa.
FRICTION

Wilson's experiments described above, Wilson fully verified these conclusions, the ratio of the pressures corresponding to the varying degrees of moisture being as follows:

<table>
<thead>
<tr>
<th>Percentage of Water</th>
<th>0.0</th>
<th>6.0</th>
<th>12.0</th>
<th>17.0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mean ratio of horizontal to vertical</td>
<td>-211</td>
<td>-212</td>
<td>-218</td>
<td>-219</td>
</tr>
</tbody>
</table>

It is of interest to note that the minimum value of the ratio is obtained when the interstices are half filled with water. It is clear, therefore, that in the design of masonry dams or retaining walls to withstand earth pressure, the use of Rankine's formulas with a value of the angle of repose determined from experiments on the dry material will give a result which is on the safe side.

§ (36) The Kinetic Friction of Dry Solid Surfaces.—As mentioned above, when once sliding has commenced between the surfaces of two bodies in contact, there is in the majority of cases a sudden fall in the amount of the frictional resistance so that the coefficient of kinetic friction for two substances is usually less than the coefficient of static friction. Jenkins and Kaying have shown that for hard substances such as steel on steel the two coefficients are equal, but when one or both surfaces are of relatively softer material, such as brass or greenheart, the coefficient of kinetic friction is less than that of static. They also found that when the two coefficients differ, the change, at low speeds at any rate, is not instantaneous at the instant at which relative motion begins, but takes place gradually and without discontinuity. Causes have been noted by Kinnell in which the coefficient of kinetic friction is greater than that of static friction. Leather on cast iron appears to be an instance of this. A marked falling off in the value of the coefficient of kinetic friction as the relative speed of sliding is increased appears to be a universal characteristic of dry sliding surfaces. There is also in many cases a further progressive fall in the value of the coefficient with time which is probably due to the abrasion of the surfaces tending to produce greater smoothness.

(i.) Experiments on Brake Blocks. Both of these characteristics are noticeable in the results of Captain Galton's experiments on the frictional resistance of cast-iron brake blocks on steel wagon wheels, as will be seen from Table IV.

<table>

A similar reduction in resistance due to increase of speed was found in Captain Galton's experiments on the frictional resistance of locomotive driving wheels on steel rails. These results are shown in Table V.

</table>

It may be remarked that similar speed effects in the case of locomotive driving wheels on steel rails was found by M. Poivre, but the actual values of the coefficients were about twice those given in the table. This difference was probably due to the state of the atmosphere during the trial, which is known to have a considerable effect on the frictional resistance. A common set of rules for driving wheels in different conditions as follows:

- Rills very dry—frictional resistance per ton.
- Rills very wet—frictional resistance per ton.
- Rills in ordinary English resistance 450 lbs. per
- Rills in foggy weather—f.
- 300 lbs. per ton.
- Rills in fresh and moody weather—frictional resistance 300 lbs. per ton.

(ii.) Friction of Woven Fabrics. In reproducing the use of metal as a material for braking surfaces of the brake blocks of early carriages and the clutches of motor vehicles has been in many cases discontinued owing to the discovery that woven fabric can be made which, when used as linings for bars and clutches, give a higher coefficient of friction with greater dissipation of heat with burning and sparking, and have a much greater durability than can be obtained with metals.

One of these materials is known as
Ferodo fabric, which consists of layers of woven asbestos bonded together in a special manner.

In an extensive series of tests at the National Physical Laboratory the following results were obtained:

<table>
<thead>
<tr>
<th>Material</th>
<th>Pressure Lbs./Sq. In</th>
<th>Work absorbed in Ft.-lbs./Sq. In. per Minute at 1000 Ft./Min.</th>

</tr>
<tr>
<td>asbestos com-</td>
<td>50</td>
<td>15,000</td>
</tr>
<tr>
<td>pressed</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The value of the coefficient of friction obtained and the work absorbed with Ferodo fibre at different speeds are given in Table VI.

It is claimed that the average life of Ferodo blocks on the cars and trailers of the London Electric Railway is respectively 12,000 and 22,000 miles as against 5000 for cast-iron blocks. With cast iron at 20° per tan, the economy per block per 1000 miles is given as 0.75 per cent. As many as 600 brake applications are made by each train per day, the average speed, including stops, being 17-17 miles per hour. The average mileage per set of blocks per car being 16,416.

The deceleration averages 5 feet per second per second as against 3 feet per second per second with metal block. With this increased deceleration services have been speeded up to 11-minute headways during "rush" hours. The much rapid braking of the trains has also led to a higher percentage of coasting minutes, the tests showing that coasting is as high as 38 per cent of the total running time.

Notwithstanding this high rate of braking, there has been an entire freedom from accidents to passengers, and there is also a very considerable improvement in the tyres, the surfaces of which are highly polished, and there is an entire absence of cutting and scoring. The economy in this respect is shown by the fact that the mileage of motor wheels provided with Ferodo brake blocks is approximately 35,000 per 1/4-in. radial wear of the tyre compared with 7000 in the case of metal blocks.

An illustration of the application of the fabric to a clutch is shown in Fig. 58.

§ (37) The Transmission of Power by Friction. (i) Belts.—One of the most convenient methods of the distribution of power from a central supply to a number of small machines is by means of belt or rope drives from pulleys on a line of shafting driven by the prime mover, to corresponding pulleys on the various machines. When the pulleys are at rest and no power is being transmitted, the tensions on the two sides of the belt are equal; but when the driving pulley commences to rotate, slipping of the surfaces of the pulleys over the surface of the belt is prevented by friction, and rotation of the driven pulley consequently takes place. The relation between the tensions on the two sides of the belt and the coefficient of friction of the belt on the surface of the pulley may be found as follows:

Let $\theta$ in Fig. 59 be the angle subtended by $ds$ at the centre, we have resolving along the radius

$$(T+\delta T)\sin \frac{\theta}{2} + T\sin \frac{\theta}{2} = R,$$
the normal pressure of the element of belt $ds$ on the surface of the pulley. Thus $R = T_0$. Also, resolving perpendicular to the radius

$$(T \cos \theta - T_0 \cos \phi) = \text{Friction} = \mu R = \mu T.$$ 

We have therefore $T \cos \phi = \mu R = \mu T_0$, whence by integration over the whole of contact $T_0 T / \mu = \phi$.

For leather belts working on iron pulleys $\mu$ has been found to range from 0.15 to 0.4. For wire rope running at the bottom of a grooved pulley $\mu = 0.15$. A common value for $\phi$ in the case of leather belts is 2-5 radians.

Taking $\phi = 0.3$ this gives $T_0 T / \mu = 2$, or the tension on the light side is twice the tension on the slack side. For approximate calculation of the size of a belt to transmit a given horse power $T_0 \cos \phi / \mu = 33,000$. H.P. transmitted where $v$ is the velocity of the surface of the pulley in feet per minute, $b$ the breadth, and $t$ the thickness of the belt in inches, and $T_0$ the maximum working tension of leather, which may be taken as equal to about 350 lbs. per square inch.

(5.) Effect of Slipping. Belts are not used in pairs in which a very exact velocity ratio between the driving and driven shafts is essential, on account of the tendency of the belt to slip over the surface of the pulley. There is also a definite amount of slipping which follows as a consequence of the elasticity of the belt. The amount of this slipping may be estimated as follows. The actual mass of the belt which passes any fixed point either on the light side or the slack side in unit time is the same. Let $l$ be the length of this mass when the tension is zero, and let $l, b$, and $E$ be the breadth, thickness, and modulus of elasticity of the belt. Also let $T_1$ and $T_2$ be the tensions on the light and slack sides of the belt. Then on the light side the length passing any fixed point in unit time will be $l(T_1 / \mu b)$ and on the slack side the corresponding length will be $(l + T_1 b / \mu)$, and it is evident, therefore, that these numbers will represent the velocities of the belt on the light and slack sides, i.e., the velocities on the two sides will be in the ratio of $(1 + T_1 b / \mu)$ to $(T_1 / \mu b)$. Further, it is easy to show that the velocity of the surface of the driving pulley must be equal to that of the light side of the belt, and that the velocity of the surface of the driven pulley must be equal to that of the slack side of the belt. Thus the belt comes on to the surface of the driving pulley at tension $T_1$ and leaves it at a lower tension $T_2$. It has therefore contracted while in contact with the pulley, and it is evident that the nature of this contraction must be a slip against the frictional force exerted by the pulley, with the result that the belt continues slip over the surface of the pulley to the point where it first makes contact. In the same manner the belt comes on the driven pulley at a tension $T_0$ and extension takes place gradually from the point at which contact begins to the point at which it leaves.

Now the work delivered to the driving pulley is $(T_1 - T_2) b v$ (velocity of surface of driving pulley) and the work communicated to the driven shaft is $(T_0 - T_2) b v$ (velocity of surface of driven pulley), i.e., the efficiency of power transmission is $(1 + T_1 b / \mu b)(1 + T_0 b / \mu)$, or approximately $1 - (T_0 - T_2) b / \mu b$.

Ex.—The value of Young's modulus for leather is approximately 30,000 lbs. per sq. in. Assuming $T_0 = T_1$, which will be the case when the coefficient of friction is about 0.3 and that the maximum working tension of a leather belt is 350 lbs. per sq. in., we have:

Efficiency of transmission $= 1 - 0.010 = 0.989$ per cent.

The amount of slip is therefore 1.4 per cent.

(iii.) Friction Drive.—Another instance of the transmission of power by friction is seen in the attempts which have been made to substitute a friction drive for the ordinary spur gear arrangements commonly adopted in motor cars in order to obtain variable and reverse speeds. This has been successfully carried out in the well-known "G.W.K." motor car, in which the friction gear takes the form of a metal disc driving a frictional wheel at right angles to it, the speed variation being obtained by varying the distance of the centre of the frictional wheel from the axis of the metal driving disc. Reversal of direction can, of course, be obtained by moving the driving wheel to the opposite side of the disc axis.

In the case of the "G.W.K." car the driving disc is fixed axially, while the driven wheel, which is capable of being moved along its axis to obtain the various gears, is pivoted at one end and pulled towards the driving disc by means of a spring at the other end. This is so arranged that the radial pressure between the two friction elements is lightest on top gear and increases as the gear ratio is lowered. This method has an obvious advantage over one in which the pressure between the wheels is constant at all speeds, since the amount of the pressure must be fixed to give an adequate frictional resistance at low speeds, and this means that the top gear on which 90 per cent of the running is done is used with a pressure between the wheels about three times in excess of what is necessary.

The coefficient of friction between the fibre material and the polished steel disc used in the "G.W.K." car is about 0.05. It is found in practice that it is safe to allow a peripheral pull on the driven wheel of 100 lbs. for each inch width of the frictional material irrespective of speed.

It is claimed by the makers of the "G.W.K." car that frictional transmission, in the case
of cars up to 10 or 12 h.p., has considerable advantages over the ordinary gear-box in that it is not only more simple to drive and the cost of repairs due to unsuitable handling and ordinary wear is much smaller.

§ 338. Rolling Friction.—The resistance to the motion of wheels and rollers over a smooth plane has sometimes been attributed to the inaccuracy of the surface, and it has been supposed that if these were removed, the resistance would entirely disappear, provided that both roller and plane were made of elastic materials and the load on the roller were not sufficient to cause permanent deformation of either surface. It was no doubt some hypothesis of this kind which led the earlier experimenters to the subject to denote the relations which they obtained by the term "laws of resistance to rolling."

The researches of Osborne Reynolds have, however, shown that in all cases in which surfaces roll over each other, an appreciable amount of slipping of the surfaces over each other takes place and it is the frictional resistance to this slipping which constitutes the resistance to rolling. This may be seen as follows: Since no material is perfectly hard, when a heavy roller rests on a surface, the weight of the roller will cause it to indent the surface, and the surface of the cylinder will flatten out as shown in Fig. 80. It is evident, therefore, that when rolling takes place the distance rolled through the roller in one revolution will not be the circumference of its undisturbed surface. For example, suppose that an iron cylinder rolls on an indiarubber surface across which lines have been drawn at intervals of 0-1 inch, and that as the cylinder rolls across these lines the surface of the rubber extends so that the intervals become 0-11 inch, closing up after the cylinder is past. Then the cylinder measures its circumference on the extended plane and the actual distance rolled through will be one-tenth less than the circumference. Hence, if, following Reynolds, we agree to call the distance which the roller would roll through if there were no extension or contraction, its "geometrical distance," then, in the case above, the cylinder rolls through less than its geometrical distance. On the other hand, if we have an indiarubber roller rolling on a steel surface and the surface of the roller extends 10 per cent in passing over the iron surface, it is evident that the roller will pass over a distance in one turn 10 per cent greater than its circumference. It must not be supposed, however, that, if the roller and the plane are of the same material these effects will balance each other. In the case of the flat surface the effect of the material surrounding a depression will be to stretch the material in the depression still further, whereas in the case of the rounded surface with a small flat on it the material surrounding the flat will compress the material in the flat and decrease its lateral expansion. The magnitude of this latter effect will, of course, depend on the smallness of the diameter of the roller. There are thus two independent causes which affect the progress of a cylinder which rolls on a plane, the relative softness of the materials and the diameter of the roller. These two causes will not in conjunction or in opposition according to whether the roller is harder or softer than the plane. Thus an iron roller on an indiarubber plane will roll through less than its geometrical distance, and an indiarubber roller on an iron plane will roll through a distance more than, less than, or equal to its geometrical distance, according to the relation between its diameter and softness.

(6) Slipping and Rolling.—The precise nature of the slipping action which takes place during rolling is somewhat complicated and is best studied after a preliminary consideration of the relatively simpler cases of the deformation of a soft elastic material between two parallel plates which approach and recede from each other without tangential motion. Let Fig. 61 represent the section of a block of indiarubber between the two plates when in the non-compressed state, and suppose the section to be marked with a series of vertical lines at equal intervals apart. Let the plates approach each other, compressing the rubber, which expands laterally. If there were no friction between the rubber and plates the section would remain rectangular as in Fig. 62 and the lines would still be equidistant. If, however, there be a frictional resistance between the rubber and plates which resists the lateral expansion, the section will bulge in the middle as shown in Fig. 63. The effect of the friction on the spacing of the lines will be that up to a certain distance, such as or, from the centre of the section, the friction will be sufficient to prevent slipping, there-
FRICTION

fore, up to this point the ends of the lines will preserve their original distances apart. Beyond the extremity of or slipping will commence and will go on increasing to the edge of the section. From the upwards, therefore, the distance between the ends of the lines will continually increase.

If now the surfaces gradually separate again, the lines between $a$ and $r$ will assume the same forms which they had at corresponding points of the compression, but since the portion beyond or has been extended by the compression, it will have to contract and the friction between the surfaces will oppose this contraction. Hence the lines beyond $a$ or during compression were curved outwards will gradually straighten and curve inwards as shown in Fig. 64.

It is important to note that during these two actions the smaller the coefficient of friction the greater will be the expansion of the lines during compression, and that as the work spent in friction during separation depends on the amount of this expansion, the work will obviously increase up to a certain point as the coefficient of friction diminishes.

In both of the above cases it will be seen that the directions of slipping on opposite sides of the centre are opposite to each other. In the case of a roller, however, it is evident that the material immediately in front of the centre of the surface of contact is being compressed and that behind it is being expanded. This action may be approximately represented in the case of the two plates with rubber between them by supposing the upper plate $AB$ to have been first inclined towards $G$, so that the material under $A$ was compressed and then inclined towards $D$ so as to raise the end $A$, thus causing a compression under $B$ and an expansion under $A$. The sectional lines will therefore assume the form shown in Fig. 65, and it is clear that the slipping on each side of the centre now takes place in the same direction. This shows that in the motion of rolling the whole of the slipping is in the same direction and tends to oppose the rotation. It is this slipping against the frictional resistance between the surfaces which gives rise to the resistance to the motion of the roller, and hence, as Reynolds showed, the correct denomination of the resistance is "rolling friction." The analogy of the motion of the indiarubber between the two plates with the case of a cylinder rolling in a plane surface is not, however, exact, as there is the important difference that in the latter case it is not the entire surface of a bar which is being compressed and expanded but a portion of a continuous surface in which whatever lateral extension may exist immediately under the roller, must be compensated by a lateral compression immediately in front and behind it.

The nature of the deformation caused by an iron roller moving over an indiarubber plane may be shown as follows. In Fig. 66, which represents a section through the cylinder and plane surface, the lines on the indiarubber are supposed to represent lines initially vertical and at equal distances apart. The motion of the roller is towards $B$, and $D$ and $C$ limit the surfaces on which there is no slipping. $C$ and $D$ are the limits of the surface of contact and beyond these points the rubber is laterally compressed owing to the lateral extension of the material under the roller. The lines in this region are, therefore, less than their natural distance apart. From $D$ to $r$ the material is being compressed, slipping is taking place, and the lines are convex outwards. From $r$ to $C$ there is no slipping, but from $C$ to $G$ expansion with slipping is taking place and the lines are concave outwards. It is clear, therefore, that the distance apart of the lines from $r$ to $C$ will depend on the amount of the lateral compression from $D$ onwards, and it is quite possible that this may be such that the distance between the lines from $r$ to $C$ may be equal to the natural distance, in which case, as we have seen, the roller will roll through its geometrical distance whatever the actual slipping between $D$ and $C$.

According to Reynolds this is what actually takes place when an indiarubber roller rolls on an iron plane. The actual slipping is obviously equal to the difference between the intervals between $r$ and $r'$, and the intervals at $D$ or $C$, and will always be greater than the loss of geometrical distance rolled through.

From the foregoing examination of the motion of rolling, the importance of the distinction between the real and apparent slip in all cases of rolling contact is clearly brought out, the apparent slip being defined as the difference between the circumference of the roller and the distance moved through by its centre in one revolution.

An explanation is also offered of the well-known fact that in general the lubrication of roller bearings is not attended with any beneficial effects in the way of increase of efficiency,
but may actually cause a loss of efficiency.

Thus referring to Fig. 60 it is clear that if the coefficient of friction is very great and the races would not coincide with D and C, and there would be no slipping, and hence no work would be spent in friction. On the other hand, if the coefficient of friction were zero, and the races would coincide with O and there would be no friction and no work spent in overcoming it. Therefore the work spent in friction is zero for two values of the variable 

\[ r/a \] which is the coefficient of friction, and since it is positive for all intermediate values it must pass through a maximum value. Hence for some position of \( r \) and \( r' \), i.e. for some value of the coefficient of friction, the work spent in friction is a maximum.

The above conclusions have been verified by Osborne Reynolds by direct experiment, for the details of which reference may be made to the article cited. In particular it may be mentioned that the experiments showed that a hard roller on a soft surface rolls short of its geometrical distance, whereas a soft roller on a hard plane rolls more than its geometrical distance, and that when both roller and plane are of equal hardness the roller rolls through less than its geometrical distance.

§ 30 THE PRACTICAL APPLICATION OF ROLLING FRICITION IN THE DESIGN OF MECHANICAL.—In recent years the loss of energy due to friction of the journals and thrust collars of mechanism has been greatly reduced by the use of ball and roller bearings. Contrary to expectation the insertion between the cylindrical bearing surfaces of mechanism of one or more rings of hardened steel balls running in hardened steel grooves or races so arranged that the sliding action is replaced by the rolling of the balls in the races has proved highly successful under heavy loading. As the effect of a design of incorrect type is likely to prove disastrous in practice, a brief account of conditions to be fulfilled and errors to be avoided may be gathered from the following illustrations of ball bearings which have been tried in practice with varying degrees of success.

1. Ball Bearings.—One of the earliest types is shown at A, Fig. 67. This is formed of a hardened steel sleeve with a V or rounded groove fixed to the shaft, the outer races consisting of two conical rings screwed into the bush by means of a fine thread, with the idea that the races could be adjusted for wear. Since the wear of the races takes place only on the loaded side it is obvious that any adjustment of this kind would be fatal to true running of the shaft.

This fault was remedied in the design B in which the races consisted of two conical rings screwed on the shaft, the outer stationary

Fig. 67.

portion being made flat. In this case the adjustable ring was always rotating and, therefore, the wear was fairly even all round and adjustment was possible, although, an experience has shown, quite unnecessary.

Later two plain races as shown at C, with a cage to keep the balls in position, were found to be successful, the final evolution of the race being shown at D where the races are grooved to a radius of about \( \frac{a}{2} \) that of the ball.

In the design of ball thrust bearings the races of the early types were made with 45° grooves as shown at E. The running of this type was very unsatisfactory, with much scratching of the balls. The substitution of a flat surface for one of the grooves as at F was an improvement but not altogether satisfactory. It was found, however, that balls running between two flat rings with a cage (G) to hold the balls ran quite satisfactorily. This design was still further improved from the weight-carrying point of view by substituting grooves of slightly greater radius than the ball, as in H. For certain purposes, however, the flat race is to be preferred, since, if there is any chance of the shaft getting out of line with its housing, there is less likelihood of trouble in heating and vibration. A high degree of accuracy in the manufacture of balls for ball bearings is very essential. For example, in the case of balls half an inch in diameter, Professor Goodman has found that a distortion of one-thousandth of an inch corresponds with a load of about 130 lbs. of the ball. Hence, if one of the balls in a thrust bearing is one-thousandth of an inch larger than the others, all ball will have about 130 lbs. more load upon it than the others, and probably failure will occur.

In the Sashino ball bearing (Fig. 68) the surface of the outer ring is spherical, with the centre at the axis of the shaft. There are two grooves on the inner ring, which can be tilted
to one side to allow the balls to be slipped into position, which is a considerable advantage.

There is the further advantage that such a bearing can be used on a shaft which is moving out of truth. These bearings are particularly applicable to the case of motor cars and aeroplanes where the framing is not very rigid.

(3) Safe Working Load in a Ball Bearing—From the results of his experiments, Professor Goodnan has been led to adopt the following formula for calculating the maximum working load on a ball bearing:

\[ W = \frac{L \cdot d^5}{N^2 \cdot D^3} \]

where \( W \) = maximum working load in lb.,
\( L \) = the number of balls in the bearing,
\( d \) = the diameter of the ball in inches,
\( N \) = the revolutions per minute,
\( D \) = the diameter of the ball race in inches; the diameter being taken from the point of contact of the ball with the inner race in a journal bearing, and from the centres of the balls in a thrust bearing.

The constants \( C \) and \( k \) are as follows:

For thrust bearings—

</tbody>
</table>

A comparison between the friction of an ordinary white metal bearing and that of a ball bearing is shown in Fig. 69. It will be seen that in the case of the white metal bearing the starting effort is very much greater than the normal resistance after it has been running for a considerable time. With ball bearings the reverse is the case, and this, apart from the limiting ratio of the resistances, is an additional reason for the use of ball bearings in machinery which stops and starts frequently.

For very large bearings, in which the loads are correspondingly high, it is customary to replace the balls by hardened steel rollers. The difficulties in obtaining satisfactory running are greater in these bearings than where balls are used, on account of the end thrust of the rollers brought about by very slight inaccuracies in the machining. A slight amount of end thrust in a roller bearing may increase the frictional resistance tenfold. Various devices to obviate end thrust, such as the insertion of a hardened steel ball between the ends of the roller and the face of the housing, have been tried, but without any great success.

One of the most successful roller bearings which have been recently brought out is illustrated in Fig. 70. In this the roller runs in a hardened steel cylindrical grooved ground in the sleeve with great precision, and after an extensive series of tests on it Professor Goodnan states that this is the only roller bearing which, in his experiences, is practically free from end thrust.

VI. The Relation between Friction and Heat Transmission in the Case of the Motion of a Fluid over a Surface having a Temperature Differing from that of the Fluid

The heat interchange between a solid surface and a fluid in contact with it, for a given difference of temperature between them and apart from radiation effects, will evidently be proportional to the rate at which the fluid particles are carried up to the surface, i.e. to the diffusion of the fluid in the neighborhood of the surface. This diffusion may be either (1) molecular, i.e. the diffusion of the molecules in a mass of fluid at rest, or (2) molecular diffusion, by means of the movement of small portions of the fluid in the form of eddies. The transmission of heat by molecular diffusion constitutes what is known as the thermal conductivity of the fluid, and that by molecular diffusion is usually denominated heat conduction. Now in the case of a fluid moving over a surface in laminar or streamline motion, there is no molecular diffusion between adjacent streamlines or laminae, and therefore, any transmission of heat to or from the surface in a direction normal to the streamlines must take place in the other direction. On the other hand, if the motion of the fluid is turbulent in nature, the eddies are so numerous that they carry with them a large amount of heat.
motion when the general motion of the fluid is
turbulent, and if the surface be hotter or colder
than the fluid it is clear that the heat trans-
mission between layer and surface will take
place by means of conductivity, and between the
outside of the layer and the mass of the
fluid, by eddy motion or convection. In
Part I. of this article dealing with "Vis-
cosity," §§ (1), (2), it has been shown that
in the case of laminar motion the transfer
of momentum between adjacent layers which
constitutes the phenomenon of viscosity is
affected by the internal diffusion of the fluid,
and further that in the case of turbulent
motion the corresponding phenomenon of
mechanical viscosity is due to the mass dif-
fusion brought about by the eddy-making
and turbulence. It would appear, there-
fore, that the mechanism by which the transfer
of momentum which constitutes frictional
resistance and that by which the transfer
of heat is brought about is essentially the
same whether the motion be laminar or
turbulent.

The probability of this effect was first
pointed out by Osborne Reynolds \(^1\) in 1874 in
a paper on the heating surfaces of steam
boilers. In this paper Reynolds described
an experiment in which, by blowing air through
a hot metal tube, the probable accuracy of his
theory was demonstrated by the fact that the
temperature of the issuing stream of air was
approximately independent of the speed of the
air current. The method of reasoning leading
to this conclusion may be stated as follows.
Consider the case of a fluid moving through a
parallel pipe of circular cross-section with
mean velocity \(V_m\), and let the inner surface of
the pipe be maintained at a uniform tempera-
ture \(T_1\). Then, neglecting the thermal con-
ductivity effect in the thin layer at the
boundary, and assuming all the transmission
to take place by eddy motion, the ratio of
the momentum lost by skin friction between
any two sections distant \(dx\) apart, to the total
momentum of the fluid, will be the same as
the ratio of the heat actually supplied by the
surface to that which would have been
supplied if the whole of the fluid had been
carried up to the surface.

Thus, if \(dp\) is the fall of pressure between
the sections,
\[
dT \quad \text{the rise of temperature between}
\]
\[
\text{the sections,}
\]
\[
W \quad \text{the weight of fluid passing per}
\]
\[
\text{second,}
\]
\[
V_m \quad \text{the mean velocity of the fluid,}
\]
\[
\alpha \quad \text{the radius of the pipe},
\]
\[
T_m \quad \text{the mean temperature of the}
\]
\[
\text{fluid between the sections.}
\]

\(^1\) Proceedings, Manchester Literary and Philo-

dsical Society, 1874.

Then, by the above relation,
\[
(dp)a^2 = \frac{WdT}{Wg - V_m^2 W(T_m - T_m)}
\]
The heat lost per unit area of the pipe is
\[
\left(\frac{3\alpha}{2}\right) a \cdot dp.
\]
where \(a\) is the specific heat per unit mass at
constant pressure, and if \(R\) denote the skin
friction per unit area,
\[
R = \frac{W a^2 dp}{2 \alpha a}.
\]
Hence if \(Q\) be the heat transmitted per unit
area,
\[
Q = R(T_m - T_m) V_m^3. \quad \text{(1)}
\]

It may be noted that there may be appre-
ciable divergence between the above value
of the heat transmission and that actually
observed, for, as Reynolds pointed out, "ult-
imately it is by conductivity that the heat
passes from the walls of the pipe to the fluid,
so that there will probably be in the result a
coefficient \(P/k\), where \(k\) is the coefficient of
thermal conductivity of the fluid, the form
of which must be determined by experiment."

(ii.) Experiments.—A series of experiments
were carried out by Dr. T. E. Stanton in 1875
with the object of testing the accuracy of the
above relation.\(^2\) The fluid used was water,
which was circulated through thin copper
pipes heated on the outside by means of a
steam jacket. The mean temperature of the
pipe was estimated from the value of its
coefficient of expansion and the increase in
length, the value of the surface temperature
being then calculated from the known heat
transmitted and the thermal conductivity of
water.

In making the experiments it was arranged
that the total rise of temperature should not
exceed a few degrees, and should be small
compared with the range of temperature
between metal and water. In this way, in a
series of experiments in which \(V_m\) was varied,
the value of \(P/k\) referred to above would be
approximately constant. Further, since it was
known that \(R = c V_m^3\), writing the relation (1)
in the form
\[
Q \frac{T_m - T_m}{T_m - T_m} = \frac{1}{D} \left(\alpha^2 - 1\right),
\]
where \(D\) is constant, the value of \(c - 1\) could
be obtained by the usual method of logarithmic
plotting.

On making this determination for several
sizes of tubes, and with a large range of speed
of flow as could be obtained, it was found
that the value of \(c\) was practically identical
with that found in the frictional determinations
(f.i.e. in varied from 1.82 to 1.86), and hence

\(^2\) Phil. Trans. Royal Society, Series A, etc.
the truth of the relation (1) in its most important practical aspect was fully demonstrated. The fact that the heat absorbed from a hot metal surface by a fluid flowing over it is, for a given difference of temperature between fluid and metal, nearly proportional to the speed at which the fluid moves over the surface, has been of great importance in the design of steam engine condensers, the radiators of internal combustion engines, and the heating surfaces of steam boilers. The application of the Reynolds theory to the case of the design of surface condensers for steam engines has shown that for a surface condenser of given area of cooling surface and supply of cooling water, in order to obtain the greatest velocity of flow, the length of the tube should be as great as possible, and that the most efficient design will be secured by using small tubes of as great a length as is consistent with the extreme limits of frictional resistance to flow allowed. This condition can be easily fulfilled in practice by arranging the tubes in separate compartments, through which the cooling water circulates in series, and thus the effective length of the tube can be increased to any desired amount.

It may be remarked that, if any means existed of determining the thickness of the layer in laminar motion at the boundary, a check between theory and experiment would be found as follows. Consider first the transmission of heat by eddy motion between the mass of fluid in the interior of the pipe and the outer surface of the layer in laminar motion, which may be assumed to have a velocity $U$.

Then equation (1) becomes

$$Q = \frac{R(T_s - T_f)}{V_m - U}, \ldots (2)$$

VOL. I

Again, considering the transmission through the surface layer, we have

$$Q = \frac{R(T_s - T_f)}{T_s - T_i}, \ldots (3)$$

where $T_s$ is the temperature of the surface, $T_i$ the thickness of the layer, and $R$ the coefficient of thermal conductivity.

and

$$R = \frac{U}{T_s - T_i}, \ldots (4)$$

Combining (2), (3), and (4), we have

$$Q = \frac{R(T_s - T_m)}{V_m} \cdot \frac{1}{1 + \rho(\eta / k - 1)} \text{ where } \rho = \frac{U}{V_m} \ldots (5)$$

If, therefore, the value of $\rho$ were known, it would be possible, by experiments with a fluid flowing over a surface for which the value of $R$ was always known, to obtain a check on the theory.

Unfortunately, no definite information on the value of $\rho$ is at present available. From an examination of the criterion, due to Körner, for the steady motion of fluid between two planes moving tangentially to each other, Mr. G. I. Taylor has arrived at the conclusion that in the case of a pipe $\omega V_m$ should become nearly constant as the velocity is increased, and independent of the nature of the fluid. As regards its value, the criterion of Leucx indicates that it may be approximately 0.38. Alternatively the value of $\rho$ may be calculated from equation (5) by substitution of the known values of $R$, $(T_s - T_m)$, $V_m$, $\mu$, and $k$ in carefully made experiments.

Such a series of experiments have been carried out by Dr. A. Scanneman in the case of water flowing through heated metal pipes, and the results of which are given in Table 1, together with certain of Stanton's results.

Stanton's Experiments with water flowing in copper tube 102 cm. long, 1-7 cm. diameter

206 | 5-08 | 51-45 | 39-65 | 29-0 | -217 | 16-5 | -29 |

It will be clear from the calculated values of \( p \) in the above table that the use of the values of 0.38 derived from the theory of Lorentz will not give results greatly in error. The low values of \( p \) found from Stanton’s results are probably due to the fact that they were obtained from short lengths of pipe in which the ratio of length to diameter was only 34, and that on this account the mean thickness of the surface layers would probably be appreciably less than that finally obtained at a considerable distance from the inlet.

Reverting to equation (5) it will be seen that if the value of \( \eta p/\nu \) for any particular fluid is approximately equal to unity, the agreement between the heat transmission given by equation (1) and that actually observed should be fairly close if the assumptions on which the theory is based are correct.

Now for air \( k = 1.09 C_n \),
where \( C_n \) is the specific heat at constant volume, and since
\[
\sigma = 1.4 C_n,
\]
we have
\[
\frac{b}{\sigma} = 1.14,
\]
so that experiments with air should furnish a rough demonstration of the accuracy or otherwise of the estimation of the Reynolds theory given above.

In some experiments made by Mr. J. R. Pannell \(^1\) at the National Physical Laboratory in 1912 the results given in Table II were obtained.

It will be seen that the agreement between calculated and observed heat is not satisfactory, so that assuming that no serious errors were made in the observations on which the figures in the table are based, it would appear that the assumptions on which the extended theory is based are inconsistent with the actual facts. The one whose validity may reasonably be questioned is the discontinuity between the layer at the boundary and the eddying fluid which is implied in the reasoning leading up to the theoretical equation (5).

It will be clear from the state of motion in the neighbourhood of the boundary which is indicated in the curves of Fig. 27 that no such discontinuity exists and that the two motions shake off into each other gradually. It is evident, therefore, that the matter requires further investigation before any reliable prediction of the amount of the heat transmission can be made from a knowledge of the frictional resistances of fluid and surface.

§41. Effect of Surface Roughness on Heat Transmission.—Apart from the practical value of the theory of heat transmission outlined above in giving an approximate measure of the improvement to be effected in heat transmission by increasing the speed of flow, the relation also indicates a possibility of increasing the efficiency of the transmission by increasing the coefficient of friction between fluid and surface. It is well known that by roughening the surface over which fluid is in motion the frictional resistance may be increased two or three fold. For example, in Mr. W. Froude’s experiments on the resistance of the towing of planks in water, it was found that the resistance of a surface similar to that of sandpaper was more than double that of a varnished surface under the same conditions. In experiments at the National Physical Laboratory the frictional resistance of brass pipes has been increased threefold by surfracing the inner surface by a series of sharp ridges produced by a cutting tool. It may be mentioned, however, that the application of the Reynolds theory to the case of rough surfaces is not a priori despicable, since the precise nature of the modification of the fluid motion as the surface roughness is increased is a matter for speculation, and it is by no means certain that an increase in surface roughness corresponds with an increase in the familiar which is the main factor in the heat transmitted.

For the purpose of testing the applicability or otherwise of the Reynolds theory to the case of surface roughness, a series of experiments were made at the National Physical Laboratory in 1917 on two pipes 1/4 inch diameter, of which one was in the smooth

\(^1\) Pannell, Report Advisory Committee Aeronautics, 1910-17, viii. 52.
the conditions of turbulence are similar to those which existed in the experiments described above. For example, from the characteristics of the motion of a fluid at the inlet of a pipe referred to in §6 (iii.), it would appear probable that had the experimental length of pipe in the above experiments been placed at the inlet to the pipe instead of some considerable distance from it, the effect of roughness on the heat transmission would not have been so marked owing to the absence of turbulence in this particular region. In order to investigate this more closely, a further research was carried out in which the heated surface represented the gills of an air-cooled internal combustion engine. The practical importance of this investigation will be obvious from the fact that if an improvement in heat transmission of the order of that obtained in the roughened pipe could be produced in the cooling surfaces of aircraft engines by artificial roughening, the possibility of considerable increase in efficiency and saving of weight would be opened up.

For this purpose the apparatus shown in Fig. 72 was constructed. This consisted of eight copper discs of approximately the dimensions and spacing of the gills of an air-cooled engine surrounding a cylinder of wood, and set up in a wind channel through which air could be circulated at speeds up to 10 feet per second. The method of making an experiment consisted in heating the gills by a current from a storage battery and measuring the amount of current and fall of potential along them. In this way the mean surface temperature of the gills and the amount of heat abstracted by the air could be calculated. Observations of the velocity and temperature of the cooling air were taken at the same time. The thickness of the copper gills was 0.056 mm., the external and internal diameters being 141 and 114 mm., and the pitch 8 mm.

The roughening was made by a special pair of steel dies by means of which the surfaces were corrugated into serpentine 6.5 mm. deep and 1.8 mm. pitch. A series of observations was first made on the smooth gills.
wove then taken out of the wind channel, roughened by the dies and replaced, and the experiments repeated under the same conditions of wind speed, and surface temperature as before.

The results of the two sets of observations are shown in Fig. 73, the ordinates of the plotted points being the heat abstracted in calories per second per degree difference of temperature between still and air current, and the abscissa the mean wind speed in m, per second.

It will be seen that, in complete contrast with the results of the pipe investigation, the

![Figure 73](image)

roughening had practically no effect on the heat transmission, thus indicating that for these particular surfaces the dimension in the direction of flow was so limited that the convection of momentum to the surface was not more intense for a rough than for a smooth surface. The anticipation that the conditions as regards turbulence in this case were probably similar to those existing at the inlet of a parallel channel appeared therefore to be justified. It is probable that considerable improvement in the design of the cooling surfaces of aircraft engines and radiators may yet be effected by a suitable increase in their frictional resistances, but further research is necessary before the direction in which it may be looked for is apparent.

**Fuel Calorimetry**

§ (1) Introduction.—The measurement of the calorific value of fuels is a branch of calorimetry which has been systematised in order that it may be practised by operators not possessed of the knowledge or experimental aptitude of the trained physicist and chemist. Large numbers of determinations of the calorific value of fuels are made daily, with a reasonably high degree of accuracy and constancy by a host of semi-skilled operators. The latter, however, merely follow instructions in the use of methods which involve the scientific application of fundamental principles of physics and chemistry to the solution of the problem of measuring exactly the heat evolved in the complete oxidation of readily combustible matter. The physical and chemical principles applied in Fuel Calorimetry are essentially identical with those applied in the measurement of the heat evolved in chemical reactions in general, and the methods employed are simply specialised adaptations to a restricted field of the general methods employed by the physicist in tackling the varying problems of calorimetry presented in the pursuit of physical, chemical, and physiological researches. The broad principles and general methods of
The calorimetric methods have been utilized in the determination of the heat evolved in the combustion of a fuel. There are several methods applicable to this purpose, and they are based on the accurate measurement of the heat evolved. The methods used are determined by the physical form of the fuel, and their accuracy depends on the extent to which the assumptions made in the calculations are valid.

In the case of solid fuels, the heat evolved is determined by the combustion of a known weight of the fuel, and the heat of this reaction is then calculated. For liquid and gaseous fuels, the heat evolved is determined by burning the fuel and measuring the increase in temperature of the surrounding water. The heat evolved is then calculated from the temperature rise.

In each case, the accuracy of the method depends on the assumptions made in the calculations. For example, in the case of solid fuels, the heat evolved is assumed to be equal to the heat of combustion. For liquid and gaseous fuels, the heat evolved is assumed to be equal to the heat of vaporization of the fuel.

The accuracy of the method is also affected by the physical form of the fuel. For example, solid fuels are easier to measure than liquid or gaseous fuels, and the heat evolved in the combustion of a solid fuel is more accurately determined.

In conclusion, calorimetric methods are a valuable tool for determining the heat evolved in the combustion of a fuel. They are accurate and reliable, and they can be used to determine the heat evolved in the combustion of a wide variety of fuels.
heat from the combustion of the gas, it is possible to produce a calorimeter which automatically registers any variations in the calorific value of the gas over a long period. The usual methods of gas calorimetry are, therefore, distinct from the usual methods of calorimetry of solid and liquid fuels, though there is some overlapping of the two methods in the calorimetry of the more highly volatile liquid fuels, such as motor-spirit, ethyl-alcohol, ether, etc. The continuous calorimetry of a supply of solid fuel, such as coal, furnishing automatically a register of fluctuations in the calorific value of that fuel, is a problem which awaits attack, and of which a satisfactory solution would be of the utmost value in industry. Even in regard to oil fuel, continuous calorimetry is practically unknown, though the problem does not present the same difficulties as that of solid fuel, and a satisfactory solution of it is not far to seek.

There are a number of points in fuel calorimetry to which consideration must be given in the case of almost all types of fuel calorimeters and of all classes of fuel. They may be classified broadly as follows: (a) Sampling the fuel; (b) Weighing or measuring the portion of the sample on which the determination is made; (c) The supply of oxygen for combustion; (d) Choice of medium for reception of the heat evolved; (e) Thermometry, or the measurement of the rise of temperature of the medium; and (f) Incidental heat losses and corrections.

§ (3) SAMPLING THE FUEL.—In general the sampling of fuel for determination of its calorific value follows the same adopted for sampling it for chemical analysis, but as many more samples of fuel are now taken for calorimetry than for analysis, and often by persons not trained in general methods of sampling, a few words on it may appropriately be said here, though, strictly speaking, sampling does not come within the scope of calorimetry as such.

There are few materials more difficult to sample properly than coal and coke, owing chiefly to the unequal distribution of earthy matter, slate, etc., in the coal as won and supplied to the consumer. Where coal or coke passes through a mechanical breaker which reduces all lumps to a relatively small size, the procedure of sampling a large bulk is greatly simplified, and if 1-cwt. portions are drawn from the outlet of the breaker at intervals corresponding with the passage through it of 6 or 8 tons, and these 1-cwt. portions are subsequently mixed, further broken, quartered, the quarter broken smaller and again quartered, a finely broken small sample is ultimately obtained from which the final sample for the determination of calorific value may be ground. This procedure answers well on gas works, etc., where coal is frequently broken before carbonisation, and coke before sintering, and coke before sintering is used for household use, but the breaking of coal before its value for most other uses and this aid to proper sampling is not generally available. In such cases larger portions, representative of both the large and the small coals, must be taken from each waggon-load, or 5 to 10 ton lot, and these portions mixed to form an average sample, a quarter of which must be roughly broken and dealt with as before. Many elaborate directions have been issued for the sampling of coal and coke deliveries, but a consideration of the particular circumstances will generally suggest the best method if it is borne in mind that the first bulk sample must be large and must be thoroughly mixed before the first quartering. Coal or loss of humidity in the course of sampling must also be avoided.

The sampling of liquid fuel is relatively an easy matter, though, with heavy petroleum oils and certain classes of tar and tar oils, stratification and deposition of solid matter are apt to occur in storage tanks, and warming by means of steam coils and stirring are needed before the sample is drawn from the tank. Liquid fuels frequently contain varying proportions of water, partly in solution and partly in suspension, and on this account a sample drawn from a single barrel is seldom representative of a consignment of many barrels. Barrels should be rolled about to agitate the contents thoroughly before they are sampled.

The sampling of gaseous fuel varies greatly in method according to the circumstances of its origin and the object of the determination of calorific value. Obviously if all that is needed is an average sample of the output of a producing plant, or of the delivery from storage vessels, different methods will be followed from those adopted if samples are required with a view to ascertaining the extreme fluctuations in calorific value of the gas produced or delivered. It may be said generally, however, that fuel gas supplies vary more in calorific value than might be expected from general knowledge of the diffusion of gases, and of processes for generating fuel gas. Even town gas supplies, derived from works where facilities for mixing and storing appear ample, quite commonly show fluctuations of 2 to 3 per cent on either side of the mean calorific value. Other fuel gases, such as acetylene produced in generators for welding and cutting purposes, are apt to vary still more in calorific value, partly owing to variations in the purity of the raw material used, and partly owing to effects incidental to the rate of generation, etc. Fortunately a continuous supply of fuel gas is generally available for calorimetry, and it is a relatively easy matter with the types of gas calorimeter commonly in use to make a number of deter-
minations, and thereby to ascertain the fluctuations in value of the gas, as well as to eliminate errors due to the taking of casual samples.

§(4) WASHING OR MEASURING THE SAMPLE.

The portion of either a solid or a liquid fuel used for a calorimetric determination will usually be weighed, but a gaseous fuel is commonly measured and the calorific value per unit weight calculated, if required, from the specific gravity of the gas. The utility of determinations of calorific value of coal, coke, etc., is largely relative to that of other lots of similar fuel, and since these fuels contain more or less free water according to the extent to which they have been exposed to rain (or underground water) or stored under cover, it is essential that the determinations of calorific value should be made on a dried sample. If the water given off in drying is determined, the calorific value of the particular lot of coal or coke in the condition in which it was when sampled can be readily calculated. Unless expressly stated otherwise, it is customary to express the calorific value of a solid fuel in terms of unit weight of the dried material. Since many coals, when finely ground and dried, are extremely hygroscopic, the precautions usually taken in weighing hygroscopic substances must be observed when weighing out the portions for calorimetry. Fuel oils, as a rule, contain very little water, but when certain grades of tar, crude petroleum, etc., are being examined it is necessary to determine the water present, which, moreover, frequently varies greatly in different samples taken from the same batch.

Gaseous fuel is usually measured saturated with water at atmospheric temperature and pressure, and the calorific value of unit volume so measured is corrected to refer to unit volumes in one or other of two standard conditions, viz.: (1) at 0° C., 760 mm. and dry, which are the normal conditions for gas measurements in scientific work, or (2) at 60° Fahn, 30 inches and saturated with water vapour, which are the normal conditions for the sale of gas in this country and generally for technical and industrial measurements of gas. The volume of gas in these conditions is only one ten-thousandth less than its volume at 15° C., 760 mm. and saturated, which are the conditions in which gas is measured for commercial and technical purposes in most continental countries.

§(5) SUPPLY OF OXYGEN FOR COMBUSTION.

The oxygen required for the combustion of the fuel in the calorimeter is obtained in most calorimeters for gaseous fuel through a supply of atmospheric air, but with solid and liquid fuel it is difficult to ensure complete and rapid combustion unless the oxygen is supplied in a more highly concentrated form. In the early calorimeters the oxygen was furnished by potassium nitrate or a similar salt, which was intimately mixed with the fuel, but with the advent of commercial supplies of oxygen compressed in steel cylinders other sources of concentrated oxygen were almost entirely displaced in calorimetry by the oxygen cylinder. Without the latter the Bunsen bomb type of calorimeter could not have come into general use. It is possible, however, to dispense with compressed oxygen if it is not available, by using a peroxide as a source of oxygen. Sodium peroxide is thus used in the Roland Wild fuel calorimeter, but there is in this case a liberation of heat from the reaction between the products of combustion and the reduced peroxide, for which a deduction has to be made from the total heat measured by the calorimeter. The uncertainty as to this deduction with fuels of a widely different ratio of carbon to hydrogen militates against the more general employment in industrial calorimetry of this convenient type of calorimeter:

§(6) MINIMUM FOR ERECTION OF THE WOODEN HUT.—The heat evolved by the combustion of the fuel is absorbed as far as possible by water in nearly all the more exact types of calorimeter. The high specific heat of water and its universal availability are the chief factors in its favour, but it has certain disadvantages which have led to the adoption in a few calorimeters of other liquids, or of air or other gas, for the absorption and measurement of the heat evolved on the combustion of the fuel. It may be said broadly, however, that the calorimeters in which water is displaced by another liquid or by a gas are of special and restricted applicability. Certain semi-automatic and recording calorimeters dispense with water, but the majority of them need calibrating against a water calorimeter owing to uncertainty as to the specific heat of the liquid or gas which is used instead of water. The water or other medium is contained in a glass or metal vessel or tube, by which and the combustion chamber or burner a portion of the heat evolved is retained. It is customary in bomb and other non-continuous calorimeters to determine experimentally the mean specific heat of these parts of the calorimeter, and to reckon their heat absorption in terms of the weight of water which would show the same rise of temperature if the same number of heat units were imparted to it. This is commonly known as the "water-equivalent" of the calorimeter, and has to be determined for each instrument. Its determination by present methods introduces an uncertainty in the results of bomb calorimetry of nearly 0-2 per cent. In calorimeters of the flow type in which a heat equilibrium becomes established, the analogous uncertainty in the results may be reduced to less than 0-1 per cent.
§ (7) Thermometry.—The rise of temperature caused by the combustion of the fuel in the calorimeter is usually measured by mercury thermometers, which are used directly or used as reference standards to check the records of some other thermometric device. Thus the degree of accuracy attainable in fuel calorimetry generally depends ultimately on the sensibility of the mercury thermometer, which when all sources of error are considered and corrections applied cannot be much higher than 0.005°, and in most cases even with high-class thermometers is not, in reality, higher than 0.01°.

The errors in thermometry in connection with bomb calorimetry have been fully discussed by C. N. Haultry in the Journal of the Society of Chemical Industry, 1910, xxix. 917, and in the Analyst, 1915, xl. 41. Briefly, the capillary tube errors may amount to, but will not exceed, one unit of the divisions if the thermometer is used without special calibration, but this may be reduced to 0.01° division or 0.005° by calibration in special cases. External and internal pressure and temporary depression of zero errors are negligible in the conditions of use of thermometers in bomb calorimetry. The other errors can best be eliminated by determining the water equivalent of the calorimeter with the same weight of water at different temperatures, and thence plotting the apparent water equivalent as a function of the temperature. In determining the water equivalent, a pure substance such as benzoic acid or pure cane sugar of which the calorific value is accurately known is burned in the calorimeter.

The errors in thermometry in connection with the use of other calorimeters in which the rate of rise of temperature measured is more than 10° comprise many of the foregoing, and others, such as that for the varying length of stem exposed to the atmosphere, which may be largely eliminated by appropriate design of the calorimeter. While the exposure of the thermometer stem to the air of the room may conceivably in certain calorimeters account for an error of as much as 0.1°, it is very rare that the error is more than one-fifth of this amount, owing to the fact that the thermometer stem is usually so situated that its temperature is more nearly that of the bulb than that of the air of the room. The correction which would otherwise be appropriate for the exposed stem of the thermometer becomes largely merged in the general correction for radiation and other heat losses from the calorimeter itself.

In all calorimetry where readings are made on two thermometers it is essential that the thermometers should be re-standardised at intervals of about twelve months until it is demonstrated thereby that there is no further change of zero through lapse of time. The artificial aging of thermometers, though of great service, is not always equally effective, and is frequently neglected even with thermometers purporting to be of high grade.

§ (8) Incidental Heat Losses.—Radiation from the instrument is, with the majority of types of calorimeter, the most important of the incidental heat losses. In the bomb type of calorimeter its effect may be eliminated (i.e., reduced to not more than 0.05 per cent) by the application of a formula, deduced from Newton's law of cooling, by Regnault, Pfannschuh, and Oussum. The following observations are needed: $T_0$, the mean temperature of the calorimeter; and $T_b$, the final temperature during the initial period; $t$, the final temperature of the principal or combustion period, and $T_d$, the mean temperature of the calorimeter during the final or cooling period. Then if $n$ is the number of minutes in the principal period, $V$, the mean loss of heat in a minute during the initial period, $V'$ the mean loss of heat in a minute during the principal period, $V''$ the mean loss of heat in a minute during the final period, and $S$ the sum of the minute readings of the thermometer during the principal period, we find for the correction $\Delta V$ the value

$$\Delta V = \frac{V'' - V_b - V}{2} + \frac{1}{1 + S}.\Delta T_0.$$
FUEL CALORIMETRY

These are the three conditions which determine the shape of the time-temperature curve, and if they are constant $S/T^2$ becomes a constant which can be ascertained once for all.

The foregoing formula eliminates also the losses due to evaporation, and the gain from the development of heat due to the friction of the air. The value of the radiation correction can be reduced to an amount which may be neglected by using in the calorimeter water a few degrees lower in temperature than the surrounding air. This method of equalising the heat transfers to and from the instrument is frequently applied in continuous water-flow calorimeters in order to render unnecessary special corrections for radiation, etc.

The heat of fusion of the ignition wire, and the heat of combustion of any cotton or collodion attached to it, are allowed for, if conditions are kept constant, in the determination of the water equivalent of the bomb calorimeter. A certain amount of nitric acid is produced from the atmospheric nitrogen initially in the bomb, or from nitrogen (if any) in the fuel, and this is fairly constant for a bomb of given capacity used on similar fuels with the same oxygen pressure, etc. It will be responsible for a liberation of 3 to 12 calories, according to circumstances, and be deducted from the observed calorific value in all the more accurate calorimetric work. A little water is put in the bomb before it is closed, and this absorbs the nitric acid formed, which is subsequently determined by titration with standard alkali, and the necessary deduction calculated accordingly. If the fuel contains sulphur, the latter is oxidised in the bomb wholly to the trioxide, which is absorbed by the water therein. It is customary to assume that in the combustion of fuel in grates and furnaces, sulphur is oxidised to sulphur dioxide only, and a deduction is accordingly made from the observed calorific value in respect of the additional heat developed in the bomb from the sulphur. The proportion of sulphur present is ascertained by a determination of the sulphuric acid in the water contained in the bomb. The assumption that sulphur in fuel, e.g. coal, when the latter is consumed in a furnace, is oxidised to sulphur dioxide only is now known to be incorrect, as sulphur trioxide is always formed also—more or less according to the furnace conditions, etc. It is, on the whole, better to omit the sulphur correction, as, at least in some cases, it is possible that very nearly the whole of the sulphur is burnt in the trioxide.

§ (9) DEGREES OF MANIPULATION. — The principal corrections and sources of error in fuel calorimetry, with the Berthelot bomb in particular, have been enumerated, and it is only necessary in regard to determinations of calorific value with the bomb to refer to one or two points in its manipulation with different types of fuels. It is usually filled with oxygen to a pressure of 25 atmospheres, but higher pressures are used with a view to securing complete combustion of coke, anthracite, and other not readily combustible fuels. The platinum or gold lining of the Berthelot bomb is replaced in the Mohler and other industrial types by an enamelled lining, which does not affect the accuracy of the results obtained as long as it remains sound, but it needs renewal from time to time. The capacity of the bombs for industrial use is generally appreciably greater than that of the platinum-lined Berthelot bomb, reaching as much as 750 c.c., as compared with 250 to 600 c.c. for the latter.

§ (10) BRIEFLY VOLATILE LIQUIDS.—The determination in the bomb of the calorific value of highly volatile liquid fuels, such as petrol, benzole, and, in particular, the motor spirits produced by the cracking of heavy mineral oil, etc., is a problem presenting special difficulties. The partial volatilisation of such liquids in the bomb leads to error in the results, due partly to the heat of evaporation of an uncertain proportion of the substance and partly to incomplete combustion of the vapour. Berthelot’s method of weighing out the volatile liquid in a small glass bulb which is sealed, or in a thin glass tube with ground-in stopper, and placing round this in the bomb a known weight of camphor, naphthalene, or other combustible of known calorific value, answers well. The ignition and combustion of the camphor expels the liquid, which is burnt with completely latent. A less satisfactory alternative, also suggested by Berthelot, is the use of a capsule of collodion, into which the ignition wire passes, for containing the volatile liquid, which is then burnt without the addition of camphor, etc. Some workers substitute celluloid for collodion.

The calorific value of highly volatile liquids may also be determined, if their latent heat of evaporation has been ascertained, by combustion of the vapour in a special lamp or burner in one of the forms of low calorimeter used for gaseous fuels, and this is the best method when large numbers of determinations have to be made on different samples of volatile liquid, e.g. motor-spirit.

§ (11) WATER-FLOW GAS CALORIMETERS.—The most widely known of the early forms of water-flow gas calorimeter is that of Junge, which, however, resembles in principle an instrument designed earlier by Harby. These calorimeters and subsequent modifications of them consist of an assembly of parallel vertical condenser tubes, down the interior of which pass the products of combustion from a gas burner, while water flows upwards round their exterior. The...
centre of the vertical cylindrical space formed by the annular water chamber of the condenser, which water chamber extends inwards at the top and forms a roof over the burner chamber. The water is supplied at a uniform rate, measured by an experimental meter of the wet type, and the rate of flow of the water, which forms a counter current to the gaseous products of combustion, is also uniform and is measured. The difference between the inlet and outlet temperatures of the water flowing through the instrument affords a measure of the calorific value of the gas, since the quantities of water and of gas supplied to it in any convenient interval of time are known. Another form of water-flow calorimeter, designed by C. V. Boys, has the water flowing through a continuous coil of tube, the heat-absorbing surface of which is increased by coils of Clarkson wire or diss joined to it by tin solder, while the products of combustion pass in a counter current through the annular spaces in which the tube is coiled. The Boys calorimeter is the standard instrument prescribed by the gas receivers for ascertaining the calorific value of town gas supplies in the United Kingdom. Various modifications of the Hartley, Jumbers, and Boys calorimeters have been introduced, especially in the United States of America, mostly with the object of eliminating possible sources of small errors, for which corrections can be readily introduced wherever the degree of accuracy of the determination in other respects warrants it. Many of these errors are wiped out automatically if the readings are made in a room of uniform temperature, and with the water supply to the instrument at a very slightly lower temperature than the air of the room. Since there is a contraction of volume on the combustion of most gases, an error is introduced if both the gas and the air supplied for its combustion are fully saturated with water vapour, due to the heat of vaporisation of the water vapour condensed from the lost volume being added to the heat directly resulting from the combustion of the gas. Atmospheric conditions of temperature and humidity in the United Kingdom are, as a rule, such that the results obtained with a gas calorimeter supplied with air which has not been artificially humidified need very little, if any, correction on account of the humidity of the air and the contraction on combustion. Errors of thermometry, as already mentioned, are common to nearly all types of fuel calorimeters, and can be eliminated in gas calorimetry by the usual precautions and corrections. Errors due to radiation and convection currents vary with the form of the gas calorimeter, and if the calorimeter room is of nearly uniform temperature, can be eliminated by the use of a correction factor, which varies slightly with the room and water temperatures. It can be determined experimentally for a particular set of working conditions.

The errors of the calorimeter proper are commonly of smaller dimensions than the error of measurement of the gas burnt in the calorimeter. This measurement has ordinarily a minimum error of one-third of 1 per cent either way, but it is quite easy to reduce this error to about 0.02 per cent, which may be taken as the possible error in the calorimeter proper when all ordinary precautions are observed. In special conditions and with exceptional precautions, the aggregate error in gas calorimetry, including the error of gas measurement, need not exceed 0.02 per cent.

§ (12) Recording Calorimeters.—Calorimeters for producing a continuous record of the calorific value of gas have been made for some years past by Jumbers and others, and in the United Kingdom the gas receiver has now required by the Gas Regulation Act to prescribe a recording calorimeter for testing continuously the calorific value of the gas supplied to consumers in all the larger towns. As a fact, however, up to the time of writing, no recording gas calorimeter has been approved as a sufficiently high degree of accuracy and trustworthiness for use in such official testing. The design of an instrument which will meet these conditions is now earnestly engaging the attention of physiologists, and several patterns are already on trial. A recording gas calorimeter should uniformly mean to: (1) furnishing a flow of gas to a burner at a known and constant rate, in terms of unit volume at normal temperature, pressure, and humidity, irrespective of fluctuations in the temperature, absolute pressure, and density of the gas; (2) furnishing a flow of water through the calorimeter at a known constant rate, irrespective of fluctuations in its temperature (and of the consequent fluctuations in its viscosity), salinity or hardness, and content of dissolved gases, and (3) measuring the difference in temperature of the water entering and leaving the calorimeter, and recording on a sufficiently open chart the product of this and the factor which for the given rates of flow of water and gas gives the calorific value of unit volume of the gas.

There are minor points, such as the effect of varying humidity of the air supplied for combustion of the gas, which have to be borne in mind in the construction of an ideal recording gas calorimeter. It is a comparatively easy matter to design an instrument which will afford a fairly precise record for, say, 24 hours, at the beginning and end of which period its indications are checked by personal observations. The problem now is to design a recording calorimeter which will automatically

**Gas Calorimeter**

- **(1) Introduction:** To measure the heat of combustion of gas some form of calorimeter is usually employed. The gas is burned at a measured rate in a special burner, which is surrounded by a coil of metal through which there is a steady and continuous flow of water. The apparatus is so arranged that the products of combustion as they rise from the burner give up practically the whole of their heat to the water. An increase in the temperature of this water is thus produced, and by measuring this increase and the total flow when the temperatures have become steady, the heat produced can be calculated. In some forms of apparatus air is used in place of water.

It is necessary to wait until a steady state has been reached, for when the apparatus is first started much of the heat is used in raising the temperature of the calorimeter itself. The fundamental quantities which it is necessary to know are the rate of flow of the gas, the quantity of water passing in a given time, and the difference in temperature between the inflowing and the outflowing water. Corrections are required, as described in the article on “Petrol Calorimeter,” for the loss of heat by radiation from the calorimeter and for the heat given out by the steam formed by the combustion in condensing to water. The escaping products of combustion, moreover, may be either warmer or colder than the gas and air entering the calorimeter; they may occupy a smaller volume and are saturated with water vapour. They may therefore contain a small quantity of heat.
due to combustion, which must be added to that found from the flow of water, or if the temperature of the water is too low it may give up heat not due to the combustion, and this must be subtracted from the calorific value found from the flow and rise of temperature of the water.

§ (2) THE STANDARD CALORIMETER OF THE GAS REFERENCE.—In Fig. 1 is shown the Boya Gas Calorimeter, the standard instrument authorised for use by the Gas Reference. The calorimeter is composed of three parts: (1) The base A, which carries a pair of acetate burners B and a regulating tap. The upper surface contains the thermometer by which its temperature is measured.

In order to maintain a uniform flow the water-supply comes from an overflow funnel fixed to the wall at a height of about one metre above the base of the calorimeter. A tube leads from this funnel to the inlet pipe of the calorimeter, and in this tube is a diaphragm with a hole about 2.3 mm. in diameter. A second tube is connected to the water-supply through a regulating tap, while a third tube, the open end of which is at a height of about two inches above the bottom of the funnel, is connected to the waste sink. The tap is opened until there is a slight trickle of water through this third pipe; thus a constant head is preserved.

The water circulates through a helix of copper tubing to the bottom of the calorimeter and then up again to the top, where it enters a temperature equalising box H; hence it passes through baffle to the out-flow box P; this contains the second thermometer, by which the temperature of the outflowing water is measured before it finally escapes as indicated in the figure. Between the outer and inner coils M and N is placed a brattice or annular partition Q containing cork dust so as to act as a heat insulator; the top of this is closed in an air-tight manner by a wooden ring which prevents the access of moisture to the cork.

The products of combustion rise in the chimney E, then pass down over the coils M between the chimney and the inner surface of the brattice, rising again in the annular space between its outer surface and the inside of the vessel D, and finally escapes through a number of holes in the lid, their temperature being measured by a thermometer fitted, as shown at G, for this purpose. Their heat is given up to the water circulating in the coils, and its amount is measured by the rise in temperature of this water as indicated by the difference between the thermometers O and P.

The steam formed by the combustion is condensed by its passage over the coils, and the water of condensation escapes by the outlet P and is measured.

§ (3) METHOD OF EXPERIMENT.—In carrying out an experiment the gas is fed to the burner through a meter and a pressure regulator. The tap of the calorimeter is regulated so that the meter hand makes one revolution in from 60 to 75 seconds. The water is allowed to flow through the calorimeter and the gas lighted; the whole is left for not less than 30 minutes for the temperatures to become steady, the thermometers being read from time to time. The escaping water passes into a change-over funnel, the position of which can be rapidly altered so as to direct the flow
combustion escape at a temperature about 1.5 above this. The water enters the cali-
meter tubes under a constant head, and the gas is controlled by a needle valve enabling a
fine adjustment to be made. In this manner a uniform flow of both gas and water is
secured.

The temperature difference is measured by a differenial air thermometer; the inlet and
outlet boxes each respectively contain, in addition to the ordinary thermometers, a thin-
wall copper box; each of these is connected by capillary copper tubing to one of a pair
of aneroid bellows; they thus form the bulbs of a differential air thermometer. The two
bellows are rigidly coupled by a connecting rod; thus the position of the red depends on
the difference of pressure of air in the two bellows, and the red moves as this pressure
difference varies.

Changes in the pressure difference are in-
dicated by a suitable mechanism attached to the red and recorded by a pen on a moving
chart. Before starting the calibrator, when
the whole apparatus is at one temperature, a
connection is opened between the bellows so
that the pressures in the two are equal; the
connection is then closed and the apparatus
started; as one of the two copper boxes is heated the pressure of the enclosed air rises
proportionately to the rise of temperature, and hence the mechanism indicates the tem-
perature difference between the outflowing and
inflowing streams.

If the chart moves uniformly and the water
flow is also maintained at a uniform rate, the
ordinates of the curve traced measure the total
heat produced.

The calibrator is put into adjustment by
determining the caloric value of the fuel in
the ordinary way by the aid of the ther-

mometers provided with the instrument;
the pen is then set at this value corrected to
normal pressure and temperature, and the
instrument gives a continuous record.

The report already quoted concludes with
the statement that "the variation of the recor-
der is seldom exceeded 2 per cent, with-
standing the fact that the temperature of the
air and water were not artificially controlled,
and there is a prospect that the limits of error
may be substantially reduced."

§ (6) The Thomas Recording Calorimeter.

—In this instrument the cooling medium is
air, not water; the gas is burned in a closed
space; the products of combustion pass down-
wards through a tube surrounding the burner.
The tube is surrounded by a second tube
through which a stream of cooling air passes
upwards; this tube is open at the top, but is
covered by a cap which forces the cooling
air to flow back outside the tube, and
finally to escape into the atmosphere. The
difference of temperature between the in-
coming and outgoing air is recorded by the
instrument, and the rate of flow being
known, and also the specific heat of air,
the total heat produced by the combustion
is obtained.

The temperature difference is measured by
two resistance thermometers connected to a
special form of Wheatstone's bridge in such a
manner that the difference between the two
resistances is recorded; the galvanometer of
the bridge acts as relay actuating the recording
mechanism. The gas to be tested, the air
required for combustion, and the cooling air
are supplied through three jet motors, which
are connected together in such a way that
the quantities supplied bear a constant ratio
to each other. These motors are partially
submerged in water in a large tank, and the
air supply is drawn from above the water
in the tank; it is thus saturated at the pre-
sure and temperature of the tank. The gas
supply passes through a governor which is also
submerged in the tank; it is subject, therefore,
to the same changes of pressure and tempera-
ture as the cooling air.

Since the quantities of gas burned and of
air employed to cool the products of combina-
tion to their initial temperature have a con-
stant ratio to each other, the rise of tempera-
ture is a measure of the total heat produced
independently of the rate of flow. The gas
and the air required for its combustion are
supplied in proper quantities by the respective
meters, and mix in a mixing chamber before
they reach the burner.

The apparatus is set by burning gas of which
the caloric value has been determined indi-
pendently; it will then record variations in the
caloric power.

GAS-CONSTANT. The ratio of the product
of the pressure and volume of any gas to its
absolute temperature which is a constant
quantity if the gas laws are assumed to hold
strictly. Its value if P is measured in atmospheres and V in cubic centimeters is

GASES, SPECIFIC HEATS OF, AT HIGH TEMPERATURES

§ (1) INTRODUCTION.—An increase in the internal energy of a gas may be accompanied not only by an increase in the linear and rotational kinetic energy of the molecules as a whole, but also (except for monatomic gases) by an increase in the intra-molecular energy of vibration of the atoms. This energy taken up in atomic vibration might be expected to increase with the temperature, thus leading to a greater increase of internal energy per degree rise of temperature, or in other words a higher molecular thermal capacity or volumetric heat, at constant volume.

All gases which are not monatomic do in fact show a specific heat increasing with the temperature. The monatomic gases should, according to the kinetic theory of gases, all have a volumetric heat which is independent of the temperature and equal to \( \frac{3}{2} R \), where \( R \) is the absolute gas constant \(-1.987\) cal. per gram mol. Moreover \( \gamma \), the ratio of the volumetric heats at constant pressure and volume, should be 1.66. Both these results have been verified experimentally. Knudt and Warburg found \( \gamma \) for mercury vapour 1.07 and Ramsay found it for argon 1.009 and for helium 1.002. Pier has measured the volumetric heat of argon up to 2900° C. by explosion experiments with oxygen and hydrogen, and up to this temperature could find no sensible variation from the theoretical value 2.096 cal. per gram molecule.

In the case of a perfect gas there can be no variation of volumetric heat with the pressure, since

\[
\left( \frac{C_p}{C_v} \right)_p = \alpha = \frac{\partial (pV)}{\partial T} \frac{1}{V}
\]

and the right-hand side of each equation is zero if \( p = 0 \) and \( T \) occur in the characteristic equation in the first degree only. In the case of air Winkler found that \( C_p \) and \( C_v \) increased with the pressure when the temperature was constant, but the variation only becomes large at very low temperatures, and above 0° C. the volumetric heats are nearly independent of the pressure. For the three diatomic gases \( N_2 \), \( O_2 \), and \( CO \), which are of importance in connection with internal combustion engines, it may safely be assumed that \( C_p \) and \( C_v \) are independent of the pressure for the range of temperature 100° C. to 30000° C.

It has been suggested 1 that the volumetric heats of \( CO_2 \) and \( H_2O \) may be dependent to an appreciable extent on pressure as well as on temperature and that they will diminish for any given temperature the greater the density. This is the reverse of what has been observed at low temperatures and, as shown below, it seems unlikely that, with \( CO_2 \) at any rate, it is so to any sensibly extent for the temperatures of 1000° C. and upwards with which one is chiefly concerned. In the case of superheated steam, for which the critical temperature is 305° C., the experiments of Knudt and Moller have shown conclusively that the volumetric heats increase considerably with the pressure for temperatures up to 500° C. Probably there is some variation with pressure above this temperature, but the amount is likely to be too small to be of any importance in internal combustion engines; according to Knudt and Jacob the variation of \( C_p \) between 2 and 8 atmospheres at 600° C. is only about 0.8 per cent, and this will probably diminish rapidly as the temperature gets well above the critical temperature. Since the critical temperature of \( CO_2 \) is some 330° C. lower than water, it seems very improbable that its volumetric heats vary appreciably with the pressure at gas-engine temperatures.

§ (2) METHODS OF MEASUREMENT.—Attempts to measure the volumetric heats of air, \( CO_2 \), and \( H_2O \) at high temperatures have been of three types.

(i.) Constant pressure experiments, in which the gas is heated externally, usually at atmospheric pressure.

1 W. T. Davd, Phil. Mag. xxix. 561.
GASES, SPECIFIC HEATS OF

(ii.) Experiments in which the change of mean temperature of a mass of gas is measured while a known amount of work is done on or by the gas. The change of temperature is calculated from the change of pressure, as measured on an indicator diagram.

(iii.) Explosion experiments, the gases being kept at constant volume.

The principal measurements in the constant pressure class (i.) have been made by Regnault,1 Wiedemann,2 Holborn and Austen,3 Holborn and Henning,4 and Swann;5 those of class (ii.) by Dugald Clerk;6 and those of class (iii.) by Maltard and Le Chatelier,7 Langen,8 and more recently by Pier and Bjerrum.9

In April 1908 the late Professor B. Hopkinson gave,10 in his paper on "The Thermal Efficiency of Gas Engines," a curve of internal energy and temperature for the working fluid in his engine compiled from the best data at that time available. In September of the same year the Committee appointed by the British Association to investigate "Gaseous Explosions, with Special Reference to Temperature," made its first report. In this a valuable summary of the position of knowledge at that date as regards specific heats of gases at high temperature is given, together with a careful criticism of the probable accuracy of the various methods of experiment.

(i.) Constant Pressure Experiments.—The highest temperature reached in experiments of the constant pressure type is 1400° C., by Holborn and Henning, and it is doubtful whether anything higher could usefully be attempted owing to the very great technical difficulty of carrying out constant pressure experiments at these high temperatures.12 Since 1908 the results of Swann's experiments on air and CO₂ have been published, and although they were only made at 20° and 100° C., they are important as giving a reliable datum-line figure for the volumetric heats at ordinary temperatures. The Gaseous Explosions Committee accepted Swann's values as correct to 1 per cent, as follows:

13 "Combustion, 18, § (74),

range of temperature as those of Holborn and Henning and gave results about 10 per cent. higher for the mean volumetric heat. The accuracy of results from these experiments depends very largely on a correct allocation of heat loss to the cylinder walls between the compression and expansion strokes. Clerk first assumed the loss during the two strokes to be the same except for the difference of mean temperature of the gas, but this is now known to be very far from true, and the difference accounts in part for the high values obtained for the volumetric heat. In order to obtain reliable results from experiments of this type it is necessary to know more of the condition of the surface layers of gas near the cylinder walls during compression and expansion.

(iii.) Explosion Experiments.—The majority of attempts to measure volumetric heats at really high temperatures have been by the explosion method, in which a known mixture of gases enclosed in a vessel of constant volume is heated by internal combustion. The temperature after explosion is inferred from the rise of pressure, and from this and the known heat of combustion of the constituent gases, a value is obtained of the mean volumetric heat of the vessel contents between the initial and final temperatures.

In interpreting the results of experiments of this kind there are several points of importance to consider:

(a) The correctness of the volumetric heats by this method depends entirely on an accurate allowance being made for any loss of energy by conduction of radiation up to the point of maximum pressure.

(b) The maximum temperature inferred from the maximum pressure is a mean temperature for the volume of gases. The actual temperature range within the gas is very wide; Hopkinson14 has estimated as much as 1000° to 1100° C. when the mean from pressure observations was 1000° C. If the specific heat were the same at all temperatures there would be no change of pressure during an equilibration of temperature, and Mr. S. Lec2 of Cambridge University has recently shown that, taking the estimated conditions in Hopkinson's experiment, the error from this cause is probably well under 1 per cent. and therefore less than experimental errors of measurement.

(c) The mean volumetric heats are calculated on the assumption that all the available heat of combustion has been generated in the gas at the moment of maximum pressure. That is to say that all the carbon and hydrogen are then present as CO₂ and H₂O. If any of

the gases are still uncombined, or in other words if any of the \( \text{CO}_2 \) and \( \text{H}_2\text{O} \) are dissociated at the highest temperature reached, and are present as \( \text{CO} + \text{O} \) and \( 2\text{H}_2 + \text{O}_2 \), the effect will be to lower the maximum temperature and give a higher value to the calculated volumetric heat. On this account many of the results from explosion experiments have been called "apparent volumetric heats"; meaning that any effect of dissociation is included in them so that the true volumetric heat will be lower than the "apparent" value.

It is important to notice that this use of "apparent" volumetric heats is highly misleading for two reasons: the amount of dissociation and, therefore, the apparent volumetric heat depends not only on temperature but on pressure, and will therefore vary according to the starting pressure of the experiment; and, secondly, the apparent volumetric heat of products of combustion containing both \( \text{CO}_2 \) and \( \text{H}_2\text{O} \) cannot properly be calculated from the apparent volumetric heats of \( \text{CO}_2 \) and \( \text{H}_2\text{O} \) found separately. \( \text{CO}_2 \) and \( \text{H}_2\text{O} \) have a dissociation product, \( \text{O}_2 \) in common, and the presence of one in a dissociated state will depress the amount of dissociation of the other, and vice versa. For this reason the only satisfactory method is that used in some of the recent experiments, of which results are given below, in which an excess of one of the burning elements is maintained during combustion sufficient to depress the dissociation to a negligible amount. In this way true volumetric heats are obtained.

§ (3) Results of Experiments.—Hopkinson has given, in his paper,\(^1\) figures for the mean volumetric heats of air, \( \text{CO}_2 \), and \( \text{H}_2\text{O} \) up to 800°, 1400°, and 1900° C., based on the work of Holborn and Henning, Holborn and Austin, Langen, and Clark. These figures Hopkinson considered to give the heat equivalent of the carbon dioxide at high temperatures of Holborn and Henning, and Langen.

Hopkinson's figures are as follows:

<table>
<thead>
<tr>
<th>Mean Volumetric Heat in Calories per Gram Molecule for Ranges 100° C. to 1000° C.</th>
</tr>
</thead>
<tbody>
<tr>
<td>( ^\circ \text{C.} )</td>
</tr>
<tr>
<td>( \text{CO}_2 )</td>
</tr>
<tr>
<td>( \text{H}_2\text{O} )</td>
</tr>
<tr>
<td>Air</td>
</tr>
</tbody>
</table>

The energy curves obtained from them are shown dotted in Fig. 1.

Since the above figures were given by Hopkinson, a number of values for the volumetric heats of \( \text{N}_2 \), \( \text{CO}_2 \), and \( \text{H}_2\text{O} \) have been published by Bjerrum, based upon his own and Pier's results of explosion experiments with hydrogen, carbon monoxide, and acetylene. These carry the observed volumetric heat values up to 2400° C., 2700° C., and 3800° C. for \( \text{N}_2 \), \( \text{CO}_2 \), and \( \text{H}_2\text{O} \) respectively.

![Graph showing energy curves for various gases](image)

The figures given by Bjerrum are as follows:

There is no doubt, in the light of Swan's experiments on air, that the values given by Holborn and Henning for nitrogen up to

---

2. Zeitschrift für Physik, Chemie, 1012.
1000° C. are too low. Bjerrum recommends the formula \( C_p = 4.0 + 30000 / T° \) C. given by Plot, or his most formula based on the theory of quanta, which give practically identical results up to 3000° C. and agree with Swann's value for air at 100° C.

By plotting energy temperature curves from the figures given above, and taking into account Swann's for air and \( \text{CO}_2 \) at 100° C., the following values for the mean volumetric heats between 100° C. and higher temperatures \( T° \) C., have been calculated, and are given as being probably the most accurate at this time available. When volumetric heats are given by Bjerrum for ranges 18°-6° and 110°-4°, the same figures have been assumed to hold for ranges 0°-6° and 100°-4°. In the higher ranges for water, where Bjerrum gives figures for ranges 18°-6°, the energy has been calculated from Bjerrum's figures as though water were a gas down to 0° C., and 600 cal. subtracted as the energy of the imaginary gas at 100° C.

It has recently been shown that if, using

\[
\text{Mean Volumetric Heats between 100° C. and } T° \text{ C. in Gram Calories per Gram Molecule,}
\]

these figures as true volumetric heats and Nernst's constants for the dissociation of \( \text{CO}_2 \) and \( \text{H}_2\text{O} \), the actual conditions in an engine cylinder are calculated, then results are obtained which are in excellent agreement with the best experimental engine results.

§ (4) Critical Comparison of Volumetric Heat Figures. (1) General. — Bjerrum has accepted Holborn and Heining's figures up to 1200° C., except as regards their values for nitrogen at low temperatures. This is now known to be too low, and the formula given by Plot and accepted by Bjerrum agrees with Swann's value for air at 100° C., which the B.A. Committee considered correct to within 1 percent. Holborn and Heining's results between 800° and 1400° have been considered as probably too low. Callender's opinion is that their results, although consistent among themselves, may be subject to systematic errors, making them over the range 0°-1400° C., as much as 10 per cent too low. This, however, was when Langen's explosion results were the best available for the higher temperatures. The more reasonable view now is to regard the constant pressure results as being confirmed by the recent explosion experiments, and probably accurate to 2 percent or 3 per cent up to 1200° C.

Above 1200° C. the new figures lie very much below the old, both for carbon dihydro and water. Hopkins considered that Langen's results were probably too high on account of incomplete combustion and insufficient allowance for heat loss. Part of the increase is probably accounted for, at least in the case of \( \text{CO}_2 \), by the occurrence of dissociation at the high temperature in Langen's experiments. In the experiments on which Pier and Bjerrum base their volumetric heat values, precautions were taken to prevent dissociation by having an excess of one of the combining elements present. Bjerrum's experiments were, in fact, designed with a view primarily to measuring the amount of dissociation of \( \text{CO}_2 \) and \( \text{H}_2\text{O} \) at various temperatures and pressures by comparing the pressures, and hence temperature, reached with an excess, first of nitrogen, and then of one of the combining elements, present.

§ (5) Bjerrum's Theoretical Calculations from Volumetric Heat Figures. — Taking a formula given by Einstein, and modified by Nernst and Lindemann, which expresses the distribution of energy in a complex molecule according to the theory of quanta, Bjerrum has developed an expression for the mean volumetric heat of a gas over any range of temperature. Using his own, Pier's, and Holborn and Heining's values for the mean volumetric heats, and evaluating the constants in the formula by means of them, Bjerrum found that the formula can be made to give values for the mean volumetric heat which follow closely the experimental values over the range 0°-3000° C.

In the case of \( \text{CO}_2 \) some confirmation of the volumetric heat values can be obtained from optical considerations. The formula for volumetric heat involves terms depending on the free period of internal vibration of the molecule. Values of such free periods calculated from observed values of the volumetric heat are found to show very fair agreement with the periodicities at which absorption bands occur in the spectrum of \( \text{CO}_2 \). Conversely, if the actual wave-lengths for the principal absorption bands are used in the formula, values of the volumetric heat are obtained which only differ by 3 percent or 4 per cent from observed values up to about 3000° C.

Water exhibits a highly complicated spectrum in the ultra-red region, and this has not yet been sufficiently explored to make it possible to compare the periodicities of actual...
specific pressures, the 300° C., the mean volumetric heat can be expressed by a formula of the same form as that for CO₂, but in order to make it fully applicable, it was necessary to add to the formula an additional term involving the fourth power of temperature.

0) probable accuracy of experimental results.—Of the new explosion data under review those by Pier under taken primarily with a view to using volumetric heats, those by Bjerrum containing calculations. Pier's experiments all done with initial pressure one atmosphere, Bjerrum's, on the other hand, in order to increase the amount of dissociation, at lower pressures—about one-seventh of atmosphere. The point is important in discussing the amount of heat loss from the system.

A chief cause of uncertainty in all results explosion experiments lies in estimation of heat loss during the rise to maximum temperature. Pier neglected this altogether, but, oddly, owing to his method of exploring, this does not affect the value of results. Bjerrum did a number of experiments with varying initial pressures, and, on an assumption that heat loss per cent is only proportional to pressure, has calculated the heat loss in his own and, whereas, in Pier's experiments, and has at correlations accordingly. The magnitude and reliability of these correlations are with each gas separately.

Pier's method of measuring volumetric heat was to make his explosion experiments explosive, taking as his standard of explosion the adiabatic gas argon. The specific heat of argon, according to the theoretical theory of gases, should be constant equal to 2.08 calories per gram molecule. But argon contains hydrogen and oxygen, and, though it contains hydrogen and oxygen, it is possible to prevent any sensible dissociation. Pier experiments at different starting pressures he was able to obtain figures for mean volumetric heat of both argon and water-vapor, and to show that argon, not up to 2000° C., shows no sensible departure from the theoretical value. These results depend on a knowledge of heat loss, which Pier assumed to be zero. Bjerrum has estimated the heat loss in these experiments at 1.8 per cent, and has recalculated Pier's results for the other gases on this basis, and on the assumption that the volumetric heat of argon is constant and equal to the theoretical value. It is impossible, indeed, to conceive of a variation of volumetric heat of a monatomic gas, and this assumption seems justified on experimental as well as theoretical grounds.

(i) Nitrogen.—Pier obtained the ratio between the volumetric heats of nitrogen and argon by comparing the quantities of the two inert gases present with an explosive mixture of oxygen and hydrogen when the same temperature was produced. In this case the results are therefore purely comparative, and, since heat loss may be taken as being the same under similar conditions of temperature and pressure, Pier's neglect of it does not vitiate his results except in so far as allowances must be made for differences of initial pressure. The magnitude of the loss in these experiments, in which the pressure rise takes place in about one-hundredth of a second, was, according to Bjerrum, only about 2 per cent in any case. So that Pier's comparative results for nitrogen should be accurate to the order of his experimental errors, which were about 1 per cent. On the whole it seems reasonable to expect that the figures given by Bjerrum for nitrogen are accurate to within ±1 per cent up to 2000° C., and ±2 per cent up to 2000° C.

(ii) Water-vapor.—The principal experiments on which the figures for water-vapor are based are those of Pier, carried out with initial pressure approximately atmospheric, and for which Bjerrum estimates the heat loss as 1.8 per cent. These vary the values up to 2377° C. Bjerrum has extended this range up to 3034° C. by experiments at low initial pressures (about one-seventh atmosphere), in which he estimates the loss as 14 per cent. This figure he gives with much confidence, but it must be pointed out that a difference of 2 per cent in the allowance for heat loss makes a difference of about 8.0 per cent in the volumetric heat values up to 3000° C. Indeed, in some further experiments with an excess of argon, also by Bjerrum, he finds it necessary to fix the heat loss allowance as 12 per cent in order to bring them into line with the rest of his results. This figure of 12 per cent, he says, was not improbable one, but does not any why ; possibly
it was because the argon experiments were at slightly higher initial pressures.

In estimating the probable accuracy of the figures for water-vapour, it seems, therefore, that we must allow that there may be an error of ±5 per cent up to 3000° C, and possibly more. Up to 2000° C, the uncertainty is considerably less. It seems likely that the possible error is not more than ±2 per cent or 3 per cent.

(iii) Carbon Dioxide.—In dealing with CO₂ one has the advantage, as with nitrogen, of being able to make the experiments comparative as between two inert gases, as was done by Pier. On the other hand, the rate of combustion where carbon is involved is very much lower than with oxygen and hydrogen. Pier found that the combustion of carbon monoxide was too slow to be any use except for mixtures giving a final temperature over 2200° C. He therefore used combustions of acetylene and oxygen, first with excess of oxygen, then excess of O₂, and finally with CO₂ and O₂. There is no doubt that Pier was getting very considerable loss of heat before the point of maximum pressure, as is clear from the very low value of the heat of combustion of acetylene which he calculated from his experiments.

It is certain that Pier never realised the importance of his heat losses, and was forced to suppose the formation of an ethylene compound of water and CO₂ to explain his heats of combustion of acetylene. There is some evidence that ethylidene was formed during combustion in an engine cylinder, but it is very unlikely that the quantities are as great as Pier supposed. Bjerrum, however, has accepted Pier's figures, being comparative, as substantially correct, and, as mentioned previously, they receive some confirmation from the spectrum of CO₂.

Bjerrum has extended the range of Pier's figures from 210° C to 2714° C, by explosions of CO and O₂, first with excess of CO and then of nitrogen. As before, his experiments were done first with a view to dissipation measurements, but in this case he used initial pressures of one-quarterm and one atmosphere. Using his results at these two pressures, he estimates his heat loss correction, and gives 10-0 as the mean volumetric heat from room temperature to 2714° C. The combustion time was of the order of one-tenth second as against one-hundredth second for the oxygen and hydrogen experiments, and the correction on the mean specific heat due to heat loss is in consequence as much as 15 per cent of the value given, in spite of the pressures at which he was working being higher than in the case of his experiments on water-vapour.

Pier has given the formula
\[ CO₂ = 0.083 + 3.8 \times 10^{-2} - 0.056 \times 10^{-6} + 0.1 \times 10^{-8} \]
as representing his experimental results upon CO₂ up to 2110° C. This formula gives 10-75 for the range up to 2714° C, so that there is good agreement between Bjerrum's and Pier's figures.

An idea of the optical confirmation of the CO₂ figures may be given as follows. The internal or vibrational energy of a triatomic molecule will be shared between the three mutual vibrations of the three atoms, (1) with (2), (2) with (3), and (3) with (1). In the case of CO₂ since the mutual attraction between a carbon and oxygen atom may be supposed greater than between the two oxygens, it is a reasonable assumption that of the three vibrations, there will be two of high frequency and one of lower. If the three wave-lengths \( \lambda_1, \lambda_2, \) and \( \lambda_3 \) of the Neum-Neumann quanta function which occurs in the volumetric heat formula are evaluated from observed values of the volumetric heat on the above assumption that \( \lambda_3 = \lambda_1 \) the values obtained by Bjerrum are \( \lambda_3 = 8.1, \lambda_2 = 2.7 \). With these constants the formula gives values of the volumetric heat which follow the actual values closely over the range 0°-2000° C, e.g.:

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>0-200</td>
<td>7-48</td>
<td>7-44</td>
<td></td>
</tr>
<tr>
<td>0-2110</td>
<td>10-47</td>
<td>10-43</td>
<td></td>
</tr>
</tbody>
</table>

Now there are actual absorption bands in the spectrum of CO₂ at \( \lambda_1 = 147 \), \( \lambda_2 = 4.3 \), and \( \lambda_3 = 2.7 \). If these values are put into the formula and the volumetric heats calculated from purely optical data, the volumetric heats for the same ranges as above are 7-67 and 10-64. The optical data, therefore, give values within 3 per cent or 4 per cent of the observed ones, and on the whole it is probable that the latest values of the volumetric heat given by Bjerrum up to 2700° C. may be taken as correct to ±3 per cent or ±4 per cent.

GYROSCOPE

§ (1) DESCRIPTION OF THE GYROSCOPE. INERTIA AND BALANCE.—The gyroscope consists mainly of a massive wheel or disc mounted on bearings so as to be free to spin rapidly about its axis of symmetry. The gyroscope as commonly made is symmetrical about an equatorial plane, perpendicular to the axis of symmetry; but this equatorial symmetry is unessential. Any rigid homogeneous solid of revolution may form the spinning element; and, more generally still, the gyroscope may even be irregular in form provided that it is "dynamically symmetrical" about the axis of spin. The conditions necessary for dynamical symmetry are (i.) that the centre of mass 0 of the gyroscope shall lie on the axis of spin; (ii.) that the axis of spin shall be a principal axis of inertia; (iii.) that the moments of inertia about all axes (through 0 perpendicular to the spin-axis (say, all "diameters") shall be equal. If any body were taken of irregular form with centroid 0, and with unequal moments of inertia A, B, C about its mutually perpendicular principal axes through 0, and if it were mounted to spin about the C axis, it would differ from the normal gyroscope only in having A and B unequal instead of equal.

In the practical making of gyroscopes the closest approximate symmetry of form is found inadequate to secure these conditions of dynamical symmetry, and a final process of "tempering" is requisite to make the gyroscope run smoothly at high speed. If, in violation of condition (i.), the centroid is not on the spin-axis, but at a short distance from it, the gyroscope is said to be defective in "static balance." With this defect, if the gyroscope is without spin the equilibrium under gravity fails to be neutral (except when the axis is vertical); and when the gyroscope spins about the fixed axis a revolving centrifugal force is thrown on the bearings. A true circular disc, mounted eccentrically on a spin-axis normal to its plane, illustrates the state of bad static balance.

If, in violation of condition (ii.), the principal axis of inertia is not coincident with the spin-axis, but makes a small angle with it, the gyroscope is said to be defective in "dynamic balance." The defect cannot be detected statically; but, when the gyroscope spins, a torque in a revolving axial plane is thrown on the bearings. A true circular disc mounted eccentrically but obliquely on a spin-axis illustrates the state of bad dynamic balance.

The two defects are both remedied by the addition or removal of small masses of determinable amount and position; and when balanced to run quietly in this way the gyroscope is usually regarded as satisfying all the necessary conditions. But, in violation of condition (iii.), the moments of inertia about different diameters of the gyroscope may be slightly unequal. An elliptical disc mounted eccentrically and normally on its spin-axis illustrates this defect. The elimination of whirling stress may be regarded as having for its direct consequence the amendment of the product of inertia for every pair of perpendicular planes of which one is axial and the other is normal to the spin-axis; and in consequence the elimination ensures that the conditions (i.) and (ii.) are satisfied. But if the moments of inertia A and B are left unequal, condition (iii.) is violated and the gyroscope is defective.

The defect cannot be detected statically, nor by spinning the gyroscope about the fixed axis. It is only when the axis is itself in motion that the unessential form of the gyroscope is revealed.

§ (2) THE MOUNTING OF THE GYROSCOPE. DEGREES OF FREEDOM.—In gyroscopic mechanisms each individual gyroscope may have any number of degrees of freedom, up to the limit of six degrees, and these degrees of freedom may arise in an unlimited variety of ways. Most commonly the centroid of the gyroscope remains a fixed point, and only the three angular degrees of freedom about the centroid are left for consideration; and, an
the spinning movement accounts for one freedom, there remain only the two degrees of freedom associated with the direction of the gyro-axis $z$. These two degrees of freedom usually occur as the relative movements of three consecutive members of a chain of pieces. The gyroscopic or rotor $R$ (Fig. 1) is free to spin about its axis $z$; and this axis is coincident with the line of bearings of a ring or frame or casing $Q$, which supports the rotor $R$. The spinning freedom is thus a rotation about the line $z$. The casing $Q$ is mounted on a frame or ring $P$, so as to be free to turn about a line $y$, intersecting $z$ at $O$. The rotation of $Q$ relatively to $P$ about $y$ provides the second degree of freedom of $R$. Finally the ring $P$ is mounted on a fixed base-piece $B$ so as to be free to turn about an axis $x$, intersecting $y$ at $O$. The rotation of $P$ relatively to $B$ about $x$ provides the third degree of freedom of $R$. In the commonest form of apparatus of this sort the axes $x$ and $y$ of the ring $P$ are made perpendicular, and the axes $y$ and $z$ of the casing $Q$ are also made perpendicular, and the fixed axis $x$ is perpendicular to the horizontal base of $B$ and consequently a vertical line. The apparatus usually described as the "Wheatstone gyroscopic" is of this type (Fig. 1A).

A gyroscopic mounted in this way, with complete angular freedom, is sometimes spoken of as a "free" gyroscopic. If the hinge-line $x$ is locked the gyroscopic has only two degrees of freedom, and is then often described as "constrained." The gyro-axis $z$ is then restricted to move in a circular cone with $y$ as axis and $y=0$ as angle. Very specially (and commonly) $y$ is a right angle, and $z$ is thus restricted to move in a fixed plane normal to $y$. (In the Wheatstone gyroscopic the gyro-axis then turns round a fixed horizontal axis.) If the hinge $y$ is locked and $x$ is left free then, similarly, the gyroscopic has only two degrees of freedom, and $z$ is restricted to describe a circular cone about $x$ (or a plane normal to $x$).

More generally the gyro-axis $z$ might in any way be left free, by mechanical constraints applied to the casing $Q$, to move only along a definite route (generating a curve of arbitrary form), and the gyroscopic would again have two degrees of freedom.

It is to be observed that the reduction from three degrees of freedom to two degrees may occur without the suppression of the freedom of rotation about $x$ or $y$. The complete angular freedom of the gyroscopic arises from the fact that any angular rotation about $O$ may in general be derived as the resultant of suitable components about $x$, $y$, and $z$. This fails to be true, however, when $x$, $y$, and $z$ happen to be coplanar; and this occurs for each of two positions, when the relative rotation of $P$ and $Q$ brings the planes $xy$ and $yz$ into coincidence. For angular velocities about coplanar lines have as their resultant an angular velocity about a line lying necessarily in the same plane. For the Wheatstone mounting, (Fig. 1A), $x$ and $z$ themselves coincide in these two positions (when the gyro-axis is vertical), and the loss of freedom is often attributed to the identity of the two rotations about the coincident lines; but the identity, though sufficient to account for the loss, is not essential. (The proposal to avoid the danger of this loss of freedom, when three degrees of freedom are to be preserved, by adding an extra member $N$ to the chain of pieces $PQR$ introduces a fresh objection; for the links $N$, $P$, $Q$ of the chain $BNQRP$ then have an indeterminate position for any one direction of $z$, and would move about at random.)

The case of a gyroscopic with only one degree of freedom, as for $x$ and $y$ both locked, leaving the spinning movement about $z$ as the sole freedom, should be mentioned as the ultimate and simplest form of freedom; but it has no gyroscopic importance.

If abstraction be made of the directions of the three axes $x$, $y$, and $z$ of the gyroscopic apparatus, without regard to position in space or any other detail, a unit sphere centred at $O$ and cutting the lines $x$, $y$, $z$ at points $X$, $Y$, $Z$ gives a completely representative figure on the spherical surface (Fig. 2). The fixed point $X$ represents the fixed axis of the base-piece $B$; the great-circle are $XY$ represents the ring $P$; $XZ$ represents the axis $y$ connecting the ring $P$ and the casing $Q$; $YZ$ represents the casing $Q$; and $Z$ represents the gyro-axis. To complete the figure, any arbitrary line $WV$ of the base $B$ gives a fixed point $W$, and $WVX$ represents the base $B$; and if any line $Z$ of the rotor $R$ gives the point $V$, the arc $ZV$ represents...
the rotor $R$. With this open quadrilateral $WXYZ$, with $WX$ fixed and all the sides of constant length, the complete angular freedom of $YZ$ is given by the rotation of $XY$ about $X$, of $YZ$ relatively to $XY$ about $Y$, and of $ZV$ relatively to $YZ$ about $Z$. And it is when the angle at $Y$ is zero or two right angles that the triangle $XYZ$ degenerates into a great-circle arc, and one degree of freedom is lost; $Z$ having then no movement possible except in the direction perpendicular to $XYZ$.

§ (3) EXPERIMENTAL.—As preliminary to a formal account of the kinematics and dynamics of the gyroscope, it may be convenient to state briefly the results of a number of simple experiments with the Wheatstone gyroscope. When checked by the principles developed later there will appear the reasons underlying these various movements; and there will arise also certain qualifications necessary to some of the statements that seem empirically correct. Familiarity with such experimental results is to some extent indispensable, in lack of more complete information, as a rough working knowledge of practical gyroscopes.

The experiments with the rapidly spinning gyroscope may be briefly described as follows, the degrees of freedom being as stated in each separate case:

(i.) Axis $x$ locked, $y$ free; any forces applied to $Q$. The gyroscope offers no resistance to the turning of $Q$ about $y$.

(ii.) Axis $z$ free, $y$ locked; any forces applied to $P$ or $Q$. The gyroscope offers no resistance to the turning of $P$ and $Q$ about $z$.

(iii.) Axes $x$ and $y$ both free; $B$ moved about in any manner. Then $z$ retains its original and vertical direction undisturbed. But if, during the movement of $B$, $z$ comes to coincide with $z$ (or passes very near $z$) a violent “kick” occurs and $z$ abruptly changes direction.

(iv.) Axes $x$ and $y$ both free; $z$ horizontal; a weight hung on one end of $z$ and released. Then $z$ remains horizontal, and $P$ and $Q$ rotate uniformly about $z$ at a rate proportional directly to the weight and inversely as the spin of the gyroscope. If the movement of $P$ is “hurried” by a torque applied to $P$ about $z$, the weight rises, and if $P$ is hindered, the weight descends.

(v.) Axes $x$ and $y$ both free; $z$ pointing in any direction; a smooth straight-edge is laid parallel to $z$ and pressed against the spindle. The spindle does not yield to the pressure but moves along the straight-edge in the same sense as if it were rolling along the straight-edge by reason of the spin.

(vi.) Axes $x$ and $y$ free, $z$ horizontal; forces are applied to $P$ as if to turn $P$ about $z$. The turning about $z$ is resisted and tilting of $Q$ about $y$ occurs. When $z$ reaches the vertical the resistance, after diminishing, disappears.

The angular momentum of the gyroscope is the resultant of the separate angular momenta
associated with the two component angular velocities, and is therefore compounded of \( \omega \) about the axis \( z \) and \( \omega \) about the diameter \( a \).

The rate of change of these two vectors gives rise to two separate torques or couples which, as kinetic reactions, are together equivalent to whatever system of applied forces may be acting on the gyroscope. They may be calculated separately.

The vector rate of change of any space-vector \( r \) having angular velocity \( \omega \) is given by the linear velocity of its extremity, and is compounded of \( r \) radially and \( r \omega \) normal to the vector in the plane of its movement. The angular momentum \( C \) about \( OZ \), corresponding to the vector \( r \), thus gives rise to a torque \( C \omega \) about \( OZ \) and a torque \( \omega \times C \) about \( OT \).

The angular momentum \( C \) about \( OU \) gives rise to a torque \( A \omega \) about \( OU \) and a torque \( -A \omega^2 \cos \rho \) about \( OT \), since \( \omega \cos \rho \) is the angular velocity of the triangle of \( Z \).

As the torque about \( OZ \) is \( C \omega \) it follows that the angular acceleration \( \frac{\alpha}{\omega} \) of the spin \( \Omega \) is the same as would be produced by the same torque about \( z \) if the axis \( z \) were stationary. When, however, the gyroscope is supposed to be already set spinning on frictionless bearings, or in practice to be supplied with an electric driving torque counterbalancing the resistances, the applied torque about the axis \( z \) is then zero, and hence \( C \omega \) is zero and \( \Omega \) remains constant independently of any movement imposed on the axis \( z \). (This property of a gyroscope is not true if condition (iii.) of \( \Omega \) (1) is violated. Unequal values of \( A \) and \( B \) give rise to fluctuations in the spin \( \Omega \).)

It is convenient to represent the torques by equivalent forces, acting at \( Z \) perpendicular to \( OZ \), producing the same moments as those of the torques. These forces are:

- \( A \omega \) along the great-circle tangent \( ZT \) at \( Z \).
- \( A \omega^2 \cos \rho \) along the inward normal \( ZK \) at \( Z \).
- \( C \omega \) along the normal at \( Z \).  

(Fig. 4.)

The last force \( C \omega \) has direction and sense which, if rotated through one right angle about \( Z \) in the same sense as that of the spin \( \Omega \), gives the direction and sense of the velocity \( \omega \) along \( Z \).

Of these three forces (or the torques they represent) it may be noticed that the first two are independent of the spin and of the moment of inertia \( I \), and depend only on \( A \) and on the movement of the axis \( z \). They would constitute the whole torque if either \( \Omega \) or \( \omega \) were zero. A thin rod along \( OZ \) credited with the same moment of inertia \( I \) would give rise to these same forces; or a single particle of mass \( A \) at \( Z \) would alone suffice. And the expressions \( \omega \) and \( \omega^2 \cos \rho \) are the components of the acceleration of \( Z \) along the tangent \( ZT \) and the normal \( ZK \); for \( \omega \) is the rate of change of the velocity \( \omega \) of \( Z \), and \( \omega^2 \cos \rho \) is the product of the velocity \( \omega \) and \( \omega \). 

The moment \( A \) at \( Z \) would thus give the same two forces.

§ (6) The Gyroscopic Torque. Rules for the Precession.—The torque \( C \omega \) is known as the "gyroscopic torque." It has \( OT \) for its axis and \( OZ \) for its plane. In many practical uses of the gyroscope the value of \( \omega \) is so large that this torque dominates the rest, and may be taken by itself as sufficiently representative of the whole kinematic reaction. The simple rule then is that the plane of the applied torque and the plane of precession are perpendicular planes through the axis of the gyroscope; and that the torque has a moment equal to the product of the angular momentum \( C \omega \) of the gyroscope and the rate of precession \( \omega \). A variety of rules have been proposed as indications of the sense of precession.

(a) The most common statement takes some such form as this: The precession is such that, after a precessional movement continued through one right angle, the axis of the gyroscope would coincide with the axis of the torque, and the sense of the spin would agree with that of the torque. But in practice there is a certain awkwardness and inconvenience in the need to consider a merely hypothetical position of the gyroscope.

(b) A briefer equivalent is to mark the sides of the quadrantal triangle, such as \( ZTU \), with arrows circulating round the triangle and representing the senses of Precession, Spin, and Torque in that (alphabetical) order.

(c) Rules more readily applied may be stated for forces, taken as equivalents of the gyroscopic torque. Thus, as above, if a force perpendicular to the axis of the gyroscope is applied at a point of the axis, the corresponding force-vector, when swung through a right angle in the sense of the spin, points then in the same direction and in which the point moves as a consequence of the precession. More realistically the force may be supposed actually applied to the thin smooth spindle of the gyroscope by lateral pressure of a straight-edge; and the precession then makes the spindle slip along the straight-edge; and the sense of travel is as if the spindle were rolling on the straight-edge by reason of its spin.

(d) A similar form of statement is true for a force parallel to the axis and supposed to act on the rim of the gyroscope; namely, if the force-vector normal to the wheel is carried round, as if rigidly connected with the wheel,
through one right-angle in the sense of the spin, if then indicates the precessional movement of the rim.

§ (7) KINETIC ENERGY, ANGULAR MOMENTUM, AND ENERGY.—In regard to the torques of § (5) it should be remarked that \( A\dot{\omega} \) and \( A\dot{\omega} \beta \) each \( \beta \) depend on the (surface component of the) acceleration of \( J \); and that if the acceleration be itself expressed in terms of any convenient set of components, it is only necessary to multiply each of these separate components by \( A \) in order to obtain the required torques. And similarly \( C\dot{\theta} \) depends on the velocity of \( Z \); and if that velocity presents itself as composed of any set of components it is only necessary to multiply each component by \( C \), and turn the result round through one right-angle backwards (i.e. against \( \dot{\theta} \)) about \( Z \), in order to obtain the corresponding contribution to the gyroscope torque.

Of angular momentum it should be borne in mind that, unlike linear momentum, it has only magnitude and direction and is not a located vector. The sum of the moments of the elements of a gyroscope (with its centre at rest) about any line parallel to the axis is the same as about the axis itself. The gyroscope might be replaced by another equal gyroscope with a parallel axis, inside the same casing, and the gyroscope torque would not be affected by the change. Further, if the same casing contained several gyroscopes, each spinning on an axis fixed relatively to the casing, the gyroscope torque of any movement of the casing would be the same as for a single contained gyroscope with an angular momentum equal to the vector sum of those contributed by the several gyroscopes.

The principle of energy demands that the applied forces should do work on the gyroscope equal to the increase of its kinetic energy. The forces \( C\dot{\theta} \) and \( A\dot{\theta} \) at \( Z \) acting normally to the velocity of \( Z \) along \( ZL \), do no work, and the force \( A\dot{\omega} \) does work at the rate \( A\dot{\omega} \). If the spin varies, the torque \( C\dot{\theta} \) causing the variation does work at the rate \( C\dot{\theta} \), and the sum \( A\dot{\theta} + A\dot{\omega} \) is thus the time-differential of the kinetic energy \( \frac{1}{2}(A\dot{\theta}^2 + A\dot{\omega}^2) \).

§ (8) SIMPLE CASES OF MOTION OF A GYROSCOPE.—The three torques found in § (6), which usually act in combination, may occur separately for special movements of the gyroscope.

(i.) The torque \( A\dot{\omega} \) occurs alone if \( \dot{\omega} = 0 \) and \( \dot{\theta} = \pi/2 \)—i.e. if the gyroscope has no spin and its axis is rotating in a plane. The torque \( A\dot{\omega} \) also occurs alone, initially, if \( \omega \) is momentarily zero, with any value for \( \dot{\theta} \). Hence under the action of a torque the gyro-axis moves initially in the plane of the torque itself.

The direction of motion begins to turn, however, at a rate \( (1/\lambda)\dot{\omega} \).

(ii.) The torque \( A\dot{\omega} \) occurs alone if \( \dot{\omega} = 0 \) and \( \dot{\theta} \) is constant—i.e. if the gyroscope has no spin and its axis describes a cone of any form at a uniform rate. The torque becomes the normal pressure on the guiding curve or cone. If \( \dot{\theta} \) also is constant the cone or curve is circular and the torque is constant.

(iii.) The gyrovacue torque \( C\dot{\theta} \) occurs alone if \( \dot{\omega} = \pi/2 \) and \( \dot{\theta} \) is constant—i.e. if the axis of the gyroscope rotates uniformly in a plane. It may be noticed in this case how, in detail, after a turn of the axis through an angle \( 2\alpha \) the time-integral of the torque-vector amounts for the change of momentum. The torque-vector \( C\dot{\theta} \) moves round one right-angle in advance of the axis. The mean of the vectors ranging over the angle \( 2\alpha \) is \( C\dot{\theta} \) along the angle-bisector, and the time is \( 2\alpha/C \); hence the time-integral of the torque gives a momentum \( 2\alpha C \) in a one right-angle beyond the angle-bisector of the gyro-axes.

The change of momentum is \( C\dot{\theta} \) in a direction having the same direction. In particular when \( 2\alpha = \pi \), with reversal of the axis, the change of momentum is \( 2\pi C \).

(iv.) If \( \dot{\omega} \) and \( \dot{\theta} \) are both constant, \( \dot{\omega} \) in Fig. 3 describes a circle with centre \( K \), and the triangle \( K'K' \) rotates uniformly about \( K \) as a fixed point. The axis of the gyroscope describes a circular curve of angle \( \dot{\theta} \). The torque outwards from the axis of the cone is \( C\dot{\theta} - A\dot{\omega} \) at \( \dot{\theta} \). For the constant rapid spin this is positive in sign; but if \( \omega \) were rapid also the torque, specially, is zero for the case \( C\dot{\theta} = A\dot{\omega} \) at \( \dot{\theta} \). This constant steady motion is then a free movement of the gyroscope. If, say, the stationary casing containing the spinning gyroscope is struck a heavy blow, giving an impulsive torque \( A\dot{\omega} \) about a diameter of the gyroscope, the impulse creates suddenly an angular momentum \( A\dot{\omega} \) and there ensues a continual motion of the axis \( z \) with \( \tan^2 \left( A\dot{\theta}/A\dot{\omega} \right) \) for the angle of the cone. This motion, being rapid, gives a linear effect, visually, and is generally spoken of as a "wobble"; but it is nevertheless technically a "steady motion."

The constant torque \( C\dot{\theta} = A\dot{\omega} \) necessary in general for the continual steady motion of the gyroscope is linear in \( \omega \) but quadratic in \( \dot{\omega} \). Hence, for an assigned value of the torque giving movement on the cone of angle \( \dot{\omega} \), there is a unique value of the spin for any assigned rate of precession; but two values of precession for any assigned spin are given by the roots of a quadratic equation, and may be real or coincident or imaginary. The steady motions of a top (which may be regarded as a frameless gyroscope) illustrate these results.
(v.) If the gyro-axis is guided by any smooth constraints, adequate to take any lateral pressures, the torques on the meridian and axial planes are supplied by the constraints, and the agent controlling the precessional movement of the axis has only to supply the torque \(\Delta \theta\). The gyroscopic torque falls on the rigid constraints, and the agent experiences no "gyroscopic resistance" whatever.

§ 11. Gyroscope, with Two Degrees of Freedom on a Rotating Base.—Instead of prescribing directly a movement of \(Z\) (Fig. 2) the movement prescribed may be that of \(Y\), leaving the movement of \(Z\) to ensue as a dynamical consequence. In a simple case \(YZ\) may be taken to be a quadrant, and \(XY\) also a quadrant, and \(Y\) may be made to move uniformly along its path, the great circle with centre \(X\), at the constant angular rate \(n\). The point \(Z\) is thus constrained to lie on a meridian, say, of the sphere; the meridian being \(XZ\) and rotating at rate \(n\) about the pole \(X\). If \(\theta\) is the polar distance \(XZ\) (equal to the angle \(XYZ\)) the velocity of \(Z\) has components \(\dot{\theta}\) along the meridian and \(n \sin \theta\) along \(XZ\) perpendicular to the meridian. The corresponding components of the gyroscopic torque give forces at \(Z\) equal to \(\sin \theta \Delta \theta\) along the meridian and \(\Delta \dot{\theta}\) perpendicular to it. (It is supposed that \(\Delta \theta\) and \(n\) would agree in sense if the angle \(\theta\) were reduced to zero.) The acceleration of \(Z\) as determined from its component velocities and the local rate of rotation \(n\cos \theta\) of \(XZ\) at \(Z\) (or otherwise) has components

\[
\frac{d}{dt} (n \sin \theta) \Delta \cos \theta \quad \text{and} \quad \frac{d}{dt} (n \sin \theta) \Delta \sin \theta.
\]

\(^{(1)}\)

\(\dot{\theta} - n^2 \sin \theta \cos \theta + p^2 \sin \theta = 0.
\]

\(^{(2)}\)

The position \(\theta = 0\) is a stable position if \(p^2 < n^2\), and the position \(\theta = \pi\) is unstable, and an inclined position of equilibrium exists given by \(\cos \theta = p^2/n^2\), and is stable. The position \(\theta = \pi\) is one of equilibrium but is unstable for all values of \(p/n\). (Another simple instance of the same movement occurs in the case of a magnetic needle oscillating in a horizontal plane in the earth’s field, with a soft-iron rod horizontal and perpendicular to the needle and rigidly connected with it.)

The equations \((8)\) and \((8)\) are identical if \((C/A)\sin \theta = p^2\), and hence the position \(\theta = 0\) is stable if \((C/A) > n^2\). It is unstable if \((C/A) < n^2\) and a position of equilibrium is then given by \(\cos \theta = (C/A)n^2\). The position \(\theta = \pi\) is an equilibrium position but unstable for all values of \(\pi/n\). Hence \((2)\) when \(Z\) is at \(X\) the spin agrees in sense with that of the rotation of \(XY\) about \(X\), and the position is stable provided \(\pi > (C/A)\). When \(Z\) is at \(X\) the antipodes of \(X\) the sense is opposite, and the position is always unstable. For the first case the spin is constantly so large that the inequality is amply satisfied, and the experimental results are apt to prompt an unqualified statement of stability. The inequality, however, is an essential condition.

The lateral pressure \(L\) of the meridian on the gyroaxis is given by

\[L = (2An \sin \theta - C) \Delta \theta\].

\(^{(9)}\)

The force \(L\) has a moment \(L \sin \theta\) about \(OX\), which has to be supplied by the agent responsible for maintaining the rotation. He provides therefore a variable torque \(L \sin \theta\), which is identically equal to

\[\frac{d}{dt} (An \sin^2 \theta + C \theta \cos \theta)\]

\(^{(10)}\)

the rate of increase of the angular momentum about \(OX\). Further, the agent supplies energy at the rate

\[\frac{d}{dt} [A(n^2 + n^2 \sin^2 \theta) + Cn^2]\]

\(^{(11)}\)

and this reduces as it should to \(nL \sin \theta\) in virtue of \((6)\) and \((7)\).

If the gyroscopic is originally in the unstable position \(\theta = \pi\) its axis will pass the position \(\theta = \pi/2\) with an angular velocity in \(\theta\) given by

\[-\frac{d}{dt} = (n^2 + 2(C/A)n)^2\]

\(^{(12)}\)

and the torque of resistance to the rotation of the meridian at this moment is equal to

\[Cn^2 + 2(C/A)n^2]\]

\(^{(13)}\)
GYROSCOPE 127

For a rapid spin $i$ this torque may be considerable even for a value of $i$ too small to show a visible movement of the gyroscope.

The special conditions $X = r/2$ and $Y = r/2$ involved in the above movement may be removed without alteration of the form of equation (6). The mutual inclination of the lines $x$ and $y$ and $z$ may be arbitrary; so that the point $Y$ describes a small circle uniformly about $X$, and $Z$ keeps at a constant distance from $Y$. The variable angle $XYZ$ still obeys a related-pendulum equation, and may take equilibrium values determined as before. For a rapid spin the stable position of $Z$ is that which gives the smallest value to $XYZ$.

More generally still, if $Z$ is constrained to lie on any rigid curve that is rotated uniformly at a constant rate $a$ about a fixed point $X$, it is at once apparent that the only positions of equilibrium are those for which the force along $ZX$ is either normal to the curve at $Z$ or else is zero. Hence positions of equilibrium occur at the foot of any normal drawn from $X$ to the curve (2). The exceptional case of a zero force (giving free movement of the gyroscope, with the guide out of effective action) occurs if $\cos XZ = (Ci/An)$; giving all points in which a circle centre $X$ and radius $r$ cuts the curve; or more exceptionally if $XZ = 0$ or $\pi$, which can occur only when the curve passes through $X$ or its antipodes, as in the example above treated.

It may further and more particularly be shown that the normals give stable positions for a minimum value of $XZ$ when $Ci > An$, so that the circle is unreal; and that when $Ci < An$, so that the circle is real, the stable positions are given by the minimum values of $XZ$ for points $Z$ outside the circle, and by maximum values of $XZ$ for points $Z$ inside the circle. The other equilibrium positions, reversely, are unstable. For the common cases that arise in present practice $i$ is small compared with $\theta$, the circle is imaginary, and the minimum values of $XZ$ correspond to the positions of stable equilibrium.

§ (10) GENERAL CONSIDERATIONS ON THE GYROSCOPE. -- In considering the rational of gyroscopic movements the student will be well advised to adhere very strictly to the precise correlation of cause and effect. Even when the spin is large and the gyroscopic torque is dominant the assignment of applied torque and consequent precession as proportional correlative should be followed in definite detail. In abbreviated verbal reasonings the common use of the word "tendency" is fruitful of much misunderstanding. The "tendency" is usually a movement which is regarded as prevented by a constraint; and as the removal of the constraint would generally be followed by an altogether different movement the latent confusion is extreme.

Of certain well-established statements which must be quoted only with caution and understanding a few may be cited.

"A free gyro tends to keep the axis about which it spins, unaltered in direction." The fixity of direction, in space, of the gyro-axis is not peculiar to the spinning gyroscope, but belongs equally to the non-spinning gyroscope. Indeed any line in any freely balanced body, originally free from rotation, would behave in the same way. The practical effect of the high spin is that the large store of angular momentum demands a much larger value for the time-integral of any disturbing torque to produce an assigned amount of angular displacement; so that the casual disturbing forces, if identical in the two cases, will produce much less angular displacement in the axis of the gyroscope that is rapidly spinning.

"A rapidly spinning gyroscope offers great resistance to any attempt to alter the direction of its axis." It has been seen, § (8) (v), that if a constraint supplies the gyroscope torque the agent controlling the movement finds no gyroscope opposition at all. A gyroscope mounted on a door, so as to spin in the plane of the panel, leaves the door open or shut as if the gyroscope were not spinning at all. It provides no "resistance," although its axis rotates with the door as the door swings. But a torsional stress (about a horizontal line of the door) is thrown on the hinges. If resistance is desired it can be secured (cf. § (9)) by giving the gyroscope two degrees of freedom relatively to the piece moved by the agent.

"Hurry on the precession and the top will rise in opposition to gravity." This is intended to apply to the slow precession of a top-heavy top leaning at an acute angle from the upward vertical (cf. § (8) (vj)). The spin and precessions circulate in the same sense, and the more general statement of § (8) (v) covers what is really intended. But as the effect of the forward force applied is (for the case of rapid spin) to produce an angular velocity of creation only, and no sensible increase of the rate of precession at all, the precession is, after all, not "hurried." The meaning seems to be that an attempt is to be made which would hurry the precession if the dynamics were not gyroscopic. If it is desired actually to hurry the precession the force applied to the axis must be such as to increase the gravity torque.

It may happen on occasion that the effect of "hurrying the precession is to make it slower, or even to reverse it. A simple example may be given. In the Wheatstone gyroscope
the casing $Q$ may be fitted with a weight so that in the absence of spin the axis $z$ is strictly vertical for either of two positions—one stable and the other (top-heavy) unstable. If the plane $yz$ is tilted slightly, and the gyroscope spins, a steady motion of slow precession takes place. In the top-heavy case the effect of "hurried the precession" will be to reduce the tilt, and so leave the rate of precession reduced in the same ratio; and if the precession is so much "hurried" as to annul and reverse the small tilt, then the ensuing precession is reversed in sense. Conversely, in order to produce an actual quickening of the precession it may be momentarily opposed.

The high speed given to gyroscopes in practice, with the consequent dominance of the gyroscopic torque, produces an experimental simplicity of effect which may obscure the fundamental dynamics. It would appear, e.g., that on loading one end of the horizontal axis of the gyroscope of a Wheatstone gyroscope the appropriate rate of precession is suppressed automatically, and that the axis revolves uniformly in the horizontal plane. If that were so, then neither the extra kinetic energy due to the precession, nor the new angular momentum about the vertical $z$, can be accounted for; for the attached load is supposed not to have sunk, and its weight has provided no moment about the vertical.

If this precise state of motion is to be actually obtained the proper precession must be given initially to the piece $P$. Without this provision the point $Z$ (Fig. 2) describes in fact not a horizontal great circle but a series of small cycloids with their cusps on the circle, as it generated by a trace-point on a minute wheel rolling below the circle. The mean level of the point $Z$ is below the circle by an amount that accounts for the kinetic energy of the mean rate of precession, and the mean tilt of the axis $z$ gives a component of the spin-momentum about the vertical that is equal and opposite to the angular momentum of the mean precession. The same results in kind hold good if the axis $z$ has a finite slope initially; and the case of a top abandoned with a rapid spin in an inclined position is another form of the same thing. The top appears to execute a steady motion with a precession that is not provided for it; but the actual motion of the axis includes a tremor that involves both a variable precession and a "rotation" in respect of the inclination of the axis to the vertical. (The decay of these rapid tremors, under dissipative forces of friction, etc., is usually very rapid.)

The complete exclusion of the supplementary torques that are independent of the spin. On occasion the method suffices; but it may lead to meaningless or erroneous results. In the case, § (9), of the gyroscope with an axis free to revolve in a plane that is uniformly rotated, the gyroscopic torque presents a component in the plane itself which no reaction is available to supply. The equation of motion (6) loses all but its last term, and the problem is simplified. It may be further suggested that the dynamical possibilities involved in the use of gyroscopes with moderate spins may presently be developed.

The familiar demand for an "explanation" of the gyroscopic torque of a precessing gyroscope will be found to survive repeated discussions of the phenomenon so long as they are based on the principle of angular momentum; and apparently the demand can only be met (if it need be) by the avoidance of this fundamental sophistication. If the simple case of the movement of § (8) (iii.) is considered, and if the axis of the gyroscope is at the moment pointing east and precessing to the north, and the spin is from zenith to north, then any slight portion of the top of the disc is moving northward; but on account of the precession it is located to the west of the meridian both before and after passing the summit, and so has a component acceleration to the west. The bottom of the wheel has similarly an acceleration to the east. Hence the pair of equal forces necessary to account for these accelerations constitute a couple that agrees with the known gyroscopic torque in its plane and its sense (cf. § (6) (2)). If the mass of the wheel be regarded as replaced by four particles equal in mass and equally spaced round the rim, and two equal particles equally distant from the centre and placed on the axis, so as jointly to preserve the same mass and moments of inertia, the acceleration of each particle may be readily calculated and the forces found in detail. Briefly, if the rim-masses are each $m$, and the radius $a$, then $C=4ma^2$. The accelerations of the summit and bottom, to west and east respectively, are $2ma$ (cf. § (9) (iii.)), and all the other accelerations are purely radial. Hence the parallel and opposite forces are of magnitude $2ma$, with an interval $2a$ between them, and thus give a torque $4ma^2$, which is equal to $2Cm$. If the general movement of the gyroscope is considered, in place of this very special steady motion, the additional torques, dependent on the diametral moment-of-inertia $A$, can be similarly evaluated. The use of the artifice of equivalent particles thus enables the kinetic reaction of the gyroscope to be calculated by appeal to the information supplied by the dynamics of a particle.

HEAT, CONDUCTION OF

§ (1) INTRODUCTION.—When one end of a metal bar is heated, a change of temperature can very soon be detected along the bar, due to the passage of heat through the metal. This process of transmitting heat is possessed in varying degrees by all material substances, and the phenomenon is known as the Conduction of Heat. Heat is usually distinguished from other agencies by means of which heat is propagated and which are dealt with in separate sections in this work—namely, Convection and Radiation. In the case of convection the heat is transferred by the actual movement of the heated matter, gaseous or liquid, as distinguished from conduction, in which no transfer of the matter itself is apparent. In fluids both conduction and convection seem to be processes of diffusion. In the case of conduction the action is molecular, due to the diffusion through the substance at rest of its molecules, carrying with them their kinetic energy; in that of convection it is nodal, brought about by the movement of small portions of the substance as eddies, or in other ways, thus transferring from point to point the kinetic energy of the molecules which go to form the eddy. Both conduction and convection are comparatively slow in their effects. Radiation, on the other hand, is the transfer of energy by other means and does not depend on the presence of the matter. Its velocity of propagation, whether in the form of waves of light, heat, or those used in wireless telegraphy, is, of course, enormous.

While it is convenient to adopt this classification of the agencies of heat propagation, it should be realised that the phenomena are probably closely related. For example, from the point of view of the molecular theory, it can be supposed that each molecule, as it becomes heated, affects those around it by radiation or by imparting some of its increased vibration to them by direct contact. The phenomenon of conduction might thus be regarded as a process of intermolecular radiation or convection. If the analysis is carried further by adopting the modern theory of electrons, capable of diffusing through metallic bodies and conductors of electricity, but capable only of vibration in dielectrics, the mechanism of heat conduction is reduced to diffusion in metallic bodies and radiation in dielectrics. It would be out of place here to enter on a full discussion of the mechanism of heat conduction. The theory will be referred to only so far as is necessary to enable us to deal with the practical subjects treated below. These will include a description of some typical methods of measuring conduction, together with a summary of the results obtained by various observers and some applications of the theory to conditions of heat flow which are encountered in practice.

§ (2) DIFFERENCES.—The first to give a precise definition of conducting power was Fourier, whose monumental work, Théorie analytique de la chaleur (1822), forms the basis of all mathematical treatment of the problems of heat flow.

(1) Conductivity: Steady State.—A clear conception is, perhaps, best obtained by considering a thin wall of material with parallel faces, one of which is maintained at a temperature $\theta_1$ and the other at a temperature of $\theta_2$ (Fig. 1). When the steady flow of heat has been established—that is to say, when the amount
of heat flowing into the wall through one face is equal to that flowing out from the other, none being absorbed or given up by the intervening material— it can be shown that the quantity of heat passing through the wall is proportional to the difference in temperature between the faces. The quantity also varies inversely as the thickness $x$ of the wall, and directly as the area $S$ and the time $t$, so that we have the relation

$$Q = KS \frac{T_1 - T_2}{x} = KS \frac{\partial T}{\partial x}.$$  

(1)

where $Q$ is the quantity of heat and $K$ is a constant depending on the nature of the material of the wall and which is called the "Thermal Conductivity." It is sometimes convenient to consider the thermal conductivity as being the ratio of the rate of heat flow per unit area to the fall of temperature per unit thickness. The latter quantity $(T_1 - T_2)/x$ or $\partial T/\partial x$ is called the "temperature gradient."

Following from the formula above, the unit of conductivity is defined, on the C.G.S. system, as the number of calories per second that would flow through every square centimetre of the surface of a wall of thickness 1 cm. and with a difference of 1°C. between its faces. Another unit commonly used by engineers is the British Thermal Unit per hour, per square foot, per inch thickness, per $10^8$ F. difference. To convert the C.G.S. unit into the other it is necessary to multiply by 293.

In the simple case, which has been taken above, of a wall with parallel faces kept at uniform temperatures, the surfaces of equal temperature in the material, or "isothermal surfaces," will be parallel to the faces of the wall and the lines of heat flow will be straight lines perpendicular to the faces. If, however, the material is not in the shape of a plane wall, or if the conditions of heat supply are different from those assumed, the isothermal surfaces and the lines of flow may be curved and the problem of calculating the heat flow will generally become very complicated. For such cases it is convenient to rewrite the equation in the form

$$Q = K(\theta_1 - \theta_2) \times \text{shape factor},$$  

(2)

$\theta_1$ and $\theta_2$ being, as before, the temperatures of isothermal surfaces and the "shape factor" being a constant depending on their shape and relative disposition. The shape factor has been calculated for a few simple cases, such as a sphere heated centrally and a long cylinder heated axially, and approximate values have been obtained for some other cases.

I. METHODS OF MEASURING CONDUCTIVITY

In general the conductivity of a material is obtained under conditions of steady heat flow, and, as has been indicated above, it can be determined by measuring the heat flowing through a body in a certain time, the temperature at two or more points, and the dimensions of the body. The experimental conditions suitable in particular cases depend mainly on the nature of the material to be tested. It is convenient therefore to consider separately the methods applicable to Solids, Liquids, and Gases, and to subdivide the first mentioned under three main headings, namely, pure, medium, and good conductors. Crystalline or non-isotrope solids are also dealt with separately.

§ (3) SOLID Dx INDUCTIVE $K = 0.00008$ to 0.00030. Under this head come the materials which are used for purposes of heat insulation: for example, in the walls of cold stores and the lagging of boilers. They include such materials as cork, charcoal, kieselguhr, magnesia, slag-wool, asbestos-wool, and so on. Before describing the methods of test, it is as well to get some idea of the structure of the materials and the mode of heat transfer. The materials are not homogeneous solids in the physical sense, but are loose aggregations of matter with a large number of included air-spaces. Their structure may be either...
fibrous or, as in the case of cork, cellular, but more often the materials in question are artificial aggregates of small particles or fibres. The transmission of heat through such materials does not take place solely by conduction in the solid particles. The mode of these in a certain volume of the material is relatively small, and their fine state of division gives rise to a high thermal resistance due to the number of joints contacts through which the heat has to pass.

In addition to conduction in the solid material there is the transfer of heat by radiation and convection across the air-spaces. That the former is small can be seen by considering an air-space bounded by parallel walls at absolute temperatures $\theta_1$ and $\theta_2$. The heat loss by radiation across such a space is independent of its thickness, and is proportional to $\theta_1^4 - \theta_2^4$, or where the difference is small to $\theta_1 - \theta_2$. If now a thin partition of conducting material parallel to the walls is interposed between them, it will take up a temperature intermediate between that of the walls (say, the mean temperature), and the radiation from the hot surface to the partition will be approximately one half of that previously passing between the hot and cold wall surfaces, and similarly, of course, the radiation from the partition to the cold wall. The effect of the partition is thus to reduce the heat transfer by radiation to about one half. Two partitions will reduce the radiation to about one-third, and so on.

If, for example, we take an air-space 3 inches thick, the temperature of one face being 10°C, and of the other 20°C, the heat loss by radiation for surfaces which are "solid radiators" would be about twenty times the heat loss that would take place through the air by conduction only—that is assuming all movement of the air could be prevented so that no transfer took place by convection. Nineteen partitions would thus reduce the radiation loss to about the same amount as that due to pure conduction through the air.

The equivalent subdivision of insulating materials is far greater than this.

A somewhat similar argument can be applied as regards convection, though the laws are not so well defined as those of radiation. For the case of an air-gap of 3 inches with a temperature difference of 10°C, and supposing the walls vertical, the convection loss would be of the order of seven times the loss which would be due to conduction only. By subdividing the space the convection loss may be reduced, and if the air-gaps are made small enough to render air currents impossible the heat will be transferred solely by conduction.

Thus we see that the best insulating material is one which most nearly approaches in conductivity to air. By subdividing space by small particles of matter we can reduce the heat loss due to convection and radiation until it is not appreciably different from that of pure conduction through the air, but the introduction of solid matter inevitably increases the total of the conduction losses since all solids conduct better than air. Hence it follows that there is a limit of efficiency to be reached by introducing solid material.

This is clearly shown in the results given by Pétaydé for the heat loss through slag-wool insulation of different densities (Fig. 2). It will be seen that the minimum value was obtained for slag-wool packed at 10 lbs. per cubic foot.

The conductivity of the class of poor conductors, or insulators, ranges in value from about 0.00008 to 0.00039 C.G.S. units, the best insulators having nearly twice the conductivity of air (0.00005). The values have a positive coefficient with rise of temperature which is frequent of the same order as that of air.

Some typical methods for testing such materials are described below.

(i) Spherical Shell Method—Nusselt.

Theoretically the simplest form of solid, from the point of view of conductivity measurements, is the sphere or spherical shell. The flow of heat from a source at the centre is symmetrical and follows a simple mathematical law. On the other hand, the use of a sphere generally gives rise to considerable experimental difficulties and the material has to be made up into a special shape.

However, the method has been successfully adopted by several experimenters, of whom Nusselt¹ may be taken as an example. In his apparatus the shell of material was contained between two spheres of metal. The inner one of copper, 15 cm. in diameter and 1½ mm. thick, was split into two halves which were joined with a bayonet joint so

---

¹ Förch, Ver. d. Ing., 1909, Heft 63 and 64.
as to give a smooth exterior. The outer sphere was also split into two halves held together by a flanged joint with bolts. It was of zinc 1 mm. thick and either 60 or 70 cm. in diameter. The zinc sphere was coated with paint and its temperature excess above the atmosphere did not exceed 15° C.

The space between the spheres was filled with the material under test, and a constant supply of heat was maintained electrically inside the inner sphere. The temperatures at different points in the material were obtained by means of a number of thermo-couples of iron—constantan. Care was taken to ensure that the wires of each couple for a few centimetres from the junction were led along the isothermal plane so as to avoid errors due to conduction in the wires themselves. The importance of this precaution was shown by means of an experiment with infusorial earth, in which the junctions of two thermocouples were embedded in the material at equal distances from the centre of the sphere: that is to say, in the same isothermal plane. In one case the wires from the junction were led away along the radius, and in the other at right angles to the radius (i.e. along the isothermal plane). The respective readings obtained were 74.8° C. and 116.3° C.

To obtain the temperature distribution in the material, couples were fixed along three radii at right angles to each other, four couples being arranged symmetrically on each radius. In addition to these 12 couples others were fixed at different points so that the distribution of temperature was studied with some care.

When the steady state of temperature had been reached it was sufficient to know the energy supplied to the central sphere, the temperature of two isothermal surfaces. The conductivity is then obtained from equation (2) above, the value of the shape factor being in this case $2a b b - a$, where $a$ and $b$ are the internal and external radii of the shell.1

Nusselt used the apparatus for testing a number of insulating materials such as infusorial earth, slag-wool, asbestos, powdered and slab cork, charcoal, sawdust, wool, silk, cotton. The temperature range extended from that of the atmosphere to 500° C. and the results are stated to be accurate to 1 or 2 per cent.

The packing of the material and the arrangement of the thermocouples must have been far from easy, and the apparatus does not therefore lend itself to studying the effect of different densities of packing on the conductivity. Nusselt's results are, however, in very fair agreement with those obtained with other observers, as will be seen from Table 1.

(6) Cylindrical Shell Method.—Lamb and Wilson. A cylindrical shell of material with plane ends was adopted by Lamb and Wilson2 for the purpose of determining the conductivity.

Their apparatus is illustrated in Fig. 3. The material was contained in the space between two cylindrical copper pots kept at a definite distance apart by pieces of vulcanised fibre. The inner pot contained a small motor with a fan attached to the axis. A cylindrical cylinder, open at the top and with holes at the bottom, was put inside to direct the currents of air over the inner surface of the inside pot, in the direction of the arrows. Energy was supplied electrically to a heating coil within, as well as to the motor; this constituted an internal supply of heat, which maintained the temperature within the pot at any determined upper limit. The motor and heating coil were connected in series, and leads were carried through a small hole in the lid of the pots to measure the current and the potential difference, and thus the power expended on internal heating. The outer pot was immersed in a tank kept overflowing from the water main, the lid of the pot being made into a sort of sagger, into which the incoming water ran. In this way the surface of the outer pot was kept at a uniform and constant temperature.

The outer pot was 8 inches in diameter and 16 inches high, and there was a clearance of 1 inch between the two pots. The temperatures of the pots were measured by thermocouples of copper and iron soldered at the points B and C.

Preliminary experiments with couples soldered to different parts of the copper pots had shown that the temperature distribution

---

was constant within 0.5°C, when working with a temperature difference of 25°C, hence the two thermocouples at B and C were relied on to give the temperature difference.

The shape factor in this case was taken as the ratio of the inner and outer pot respectively. The formula is an approximation, but experiments with 2-inch layers gave results consistent with those for 1-inch layers, so that it may be taken as sufficiently accurate.

### Table 1

**Poor Insulators**

The thermal conductivity $K$ is given in the Tables below as the number of calories per sq. cm. per sec. per 1°C difference in temperature.

</tbody>
</table>

The temperature difference in these experiments was about 20° or 30° C, and the results are summarized in Table 1. As in the case of the spherical shell method, the configuration of the apparatus makes it difficult to secure uniformity of packing, a point of some importance in determining the conductivity of many insulating materials. It is not clear whether the question of heat...
loss by conduction along the wire leading from the inner pot was considered.

(iii) Wall Methods. (a) Randolph. In using the wall method it is assumed that the lines of heat flow are perpendicular to the face. This is true for the central portion of a wall, but at the edges, unless the thickness of heat laterally can be prevented, the lines of flow will be curved. The "edge effect" thus produced gives rise to troublesome corrections in applying the equation (1) above, and it only becomes negligible if the wall is very large compared to its thickness. The difficulty can, however, be unamounted by the use of the guard line principle, the effect of which is to isolate a central portion of the wall where the heat flow is approximately normal to the surface.

An example of an apparatus of this kind is that designed by Randolph for measuring the conductivity of metallic materials.

He took a hot plate heated by electric current, in which a resistance ribbon wound on a mica. The top of this plate is of copper, 12 inches in diameter and 1 inch thick, and its temperature is measured by means of couples of platinum and platinum-rhodium. The material to be tested, which varied in thickness from 1 inch to 2 inches, is contained between the hot plate and a water-cooled plate. The latter is in two parts, the central one forming a calotte and the outer one a guard line. A stream of water is maintained in the calotte, and its rate of flow multiplied by the difference in temperature between the guard line and the currents gives the quantity of heat received by the central disc. A similar stream of water flows through the guard line, and its temperature is raised from 50° to 60° from the water in the calotte. With this small difference in temperature between continuous portions of the guard line and calotte, and no other metallic connection between the two, there could be no appreciable pressure of heat from one to the other. All the heat reaching the calotte was thus received directly from the hot plate, and the lines of flow were approximately normal to the surface. The conductivity was obtained from equation (1), knowing the temperatures of the hot and cold plates and the thickness of the material.

Randolph used this apparatus for obtaining the conductivity of a number of insulating materials such as muslin, and various select compositions, mineral wool, cotton, &c. A summary of his results will be found in Table III. It is interesting to note that he adopted a standard of comparison of the materials which were packed as closely as possible by tapping and were then compressed by 25 per cent. The

![Diagram](image-url)

Fig. 4.

[Text continues...]

1 foot wide, surrounding it. These portions are separated by an air-gap, and are kept apart by four small wedges of wood or felt. They are independently heated, and the energy supplied to each is adjusted so that the temperatures of the contiguous edges are the same. In order to facilitate this adjustment the energy supplied to the top, bottom, and sides of the guard-ring could be separately controlled (see Fig. 4). Under these conditions the heat flows away from the central portion in lines perpendicular to the surface. The outer surface of each wall of the material is in contact with an iron plate, which can be maintained at a constant temperature. This is effected by the circulation of water or brine through a coil of square-section lead pipe, which is clamped on to the back of the plate (Fig. 5). The plate and coil are contained in a wooden case packed with insulation, which is not shown in the figure. The coil is wound in a hillier manner, so that inflow and outflow pipes alternate, and thus the temperature is uniform over the whole surface. The cold plates can conveniently be run at any temperature from -20° C. to +15° C. The temperature distribution is studied by means of a number of thermocouples let into grooves in the hot and cold plates. By taking due precautions the plates can be kept uniform in temperature within about 0.01° C.

By means of this apparatus walls of insulating material have been tested under conditions corresponding closely to those prevailing in cold stores. Some of the results obtained are given in Table I.

§ (4) SOLIDS, MEDIUM CONDUCTORS 
(K = 0.0003 to 0.01).—The division between the poor and medium conductors is purely one of convenience. All non-metallic bodies not included in the former class fall into the latter. Examples of the medium conductors are the various kinds of woods and other organic substances, the refractory materials and bricks used in furnace construction, rocks and mineral substances. The limits of conductivity may be said to be from 0.0003 to 0.01 C.G.S. units. No general rule can be laid down as to the change of value with temperature. As may be expected, the more granular materials show an increase in conductivity with rise of temperature, while the homogeneous solids generally show a decrease.

(5) Cylindrical Method.—A number of experimenters have used a solid cylinder of material heated axially to measure the conductivity. The heat is generally supplied by a wire along the axis, and the temperature is measured at two or more points at different distances from the axis. If Q is the quantity of heat generated per unit length of the heating wire, then

\[ Q = \frac{2\pi K (\theta_1 - \theta_2)}{\ln \left( \frac{r_2}{r_1} \right)} \]

We may take as examples the experiments of Niven, Poole, Clement and Eggy.

(a) Niven.—The conductivity of a number of materials such as wood, sawdust, sand, plaster of Paris, and garden mould was measured by Niven.1

A general view of the apparatus is shown in Fig. 6, while the arrangement of the wires for heating and measuring temperature are shown in Fig. 7. For the central heating wire CD, platinoid of gauge 34 or 40 was used. The wires AA and BB were of platinum.

FIG. 5.

FIG. 6.

FIG. 7.

They were prepared by coating a platinum wire with copper and drawing down till the platinum had a thickness of 0.035 mm. and the copper 0.27 mm. The latter was then dissolved off. The change of resistance of

these wires gave the difference in temperature between the isothermal surfaces, whose distances from the axis could be accurately measured. Niven experimented considerable difficulty in the use of these fine wires, and eventually abandoned them in favour of thermo-junctions consisting of German silver wire and iron 0.2 mm. in diameter.

When solid material was being tested in this apparatus, it was in the form of two half cylinders. One of these was moved up underneath the wires until they rested on its face, and the other half-cylinder was then fixed on top. For loose materials cylindrical wooden shells were used as containers.

Niven gives an approximate calculation as to the time taken for the flow of heat to reach the steady state. Assuming the temperature to be taken at two points respectively 7 and 3 cm. from axis, and taking sand which has a diffusivity of about 0.0032, the time taken for the temperature difference to reach within 5 per cent of its final value was 1 1/4 hours, and within 1 per cent of its final value 7 1/2 hours.

A summary of Niven's results is included in Table II.

It is not clear from the description given whether any special precautions were taken to guard against "end effect" due to the conduction of heat at the ends of the heating wire and cylinder. Apart from this point the method does not seem to be open to criticism.

(b) Poole. 1—This experimenter made use of a cylinder of material for measuring the conductivity of rocks. The cylinder was heated axially by means of a wire dissipating a known amount of energy, and it was contained inside an electric furnace maintained at a constant temperature which ranged up to 600° C. Several modifications of apparatus were used, one of which is illustrated in Fig. 8.

The furnace consisted of a copper tube wound with insulated nichrome wire and contained in a lagged case. The specimen cylinder of rock A fitted roughly into the furnace, the ends of which CO were filled with pulped asbestos millboard. The cylinder was 20 cm. long by 6 cm. diameter and had a hole bored down its axis. With a soft rock such as limestone, a hole as small as 1.5 mm. diameter could be bored, but with hard rocks like granite or basalt the hole was nearer 4-5 mm. in diameter. In the latter cases the hole was either filled in with cement, through which a smaller hole could then be bored, or the platinum heating wire (0.3 mm. in diameter) was wound with asbestos card to keep it central in the hole. A constant current was passed through the wire, and the potential drop was measured on the central portion 10 cm. in length. By using a
cylinder relatively long compared to its diameter, and by measuring the energy dissipated in the portion of the wire well within the cylinder, the troublesome end effect found in preliminary experiments was eliminated. The difference in temperature of two isothermal surfaces and the mean of the temperatures of the surfaces were measured by means of couples of platinum and platinum-iridium 0.1 mm. in diameter. The couples were all in the central plane of a perpendicular to the axis, the cylinder being cut in half at this point. The arrangement of the couples is shown in Fig. 9, which is a plan of the lower half of the cylinder. The junctions of the couples are fixed in circular grooves cut in the face, the grooves being connected by radial grooves for carrying the wires between the circular grooves and for carrying them out of the cylinder. It will be seen that the couples are arranged so that the mean E.M.F. gives the mean difference in temperature of the circular grooves. The diameters of the latter were respectively 2.04 cm. and 0.725 cm. They are V-shaped, 1.5 mm. deep and 1.5 mm. wide, while the radial grooves were 0.5 mm. deep. The couple wires were cemented in the bottom of the grooves, and the two half-cylinders were cemented together. In the right-hand half-cylinder a groove was cut at a distance from the axis equal to the geometrical half of the grooves: the couple, fixed in this groove, gave the mean normal surfaces between these of 10°C, while the whole apparatus by an automatic means were made when been approximately unimportant. Small departures from the steady flow, also made use of a cylinder cut into two longitudinally instead of transversely, it has the advantage of enabling the axial couple to be made very small and accurate. Similar arrangement for determining the difference in temperature between isothermal surfaces is adopted, the junctions of the couples being, of course, in a longitudinal plane instead of a transverse plane as before.

Paul made a study of the variation of conductivity of limestone, granite, and basalt by means of his apparatus. He shows that the two former give decreases of conductivity with rise of temperature, while basalt shows a slight rise to about 200°C, above which the conductivity is constant. On prolonged heating all three materials show a permanent fall in conductivity, due apparently to small cracks in the rocks.

(a) **Clement and Egg**.—A similar method to those described immediately above was used by Clement and Egg¹ for obtaining the conductivity of fireclay bricks. The specimens were in the form of hollow cylinders heated by a coil of nickel wire wound on a porcelain tube fixed along the axis of the specimen. Two holes were bored parallel to the axis for the insertion of thermocouples.

The method has the disadvantage that specimens were required of special form differing from that in which the material is used, and there would seem to have been some uncertainty in the measurement of the radial distances.

(b) **Wall or Slab Methods**.—A number of observers have determined the conductivity of materials of medium conductivity by experiments on walls or slabs. In the important class of refractory materials, the methods adopted by Wolfgdine, Dougill, Hodsman and Cobb, Boyd-Dudley, and Griffiths are described, while for other materials the work of Lees is referred to.

(a) **Wolfgdine**.—An extended investigation of the thermal conductivity of refractory materials of French manufacture was made by Wolfgdine.²

A diagram of the apparatus he employed is shown in Fig. 10. The specimen under test was specially made in the form of a circular disc, 3 cm. in thickness, with a bevelled edge forming a portion of the walls of a gas-heated muffle. The temperature gradient through the slab was obtained by embedding two platinum-platinum-iridium couples at a depth of 5 mm. from each face. An additional thermo-element in the air near the hot face gave the furnace temperature.

The heat transmitted through the slab was measured by a flow calorimeter in the form shown in the figure.

The design of the calorimeter is the weakest point in the method, since the presence of a cooled area on the upper surface must distort the flow lines from normal. A guard-ring around the calorimeter would have eliminated this source of error.

The couples were calibrated by reference to the freezing-points of copper, common salt, and aluminium, together with the boiling-points of sulphur and naphthalene. With the exception of sulphur, the values assumed for these fixed points are in fair agreement with the values accepted at the present time. For the boiling-point of sulphur the value 455° was taken instead of the generally accepted value 445°.

In the case of each material, samples were fired at two temperatures, 1060° C. and 1300° C., and it was found that the conductivity increased with the firing temperature. Thus silica bricks fired at 1300° C. showed a value 50 per cent greater than those burned at 1060° C. Wougléman also found that thermal conductivity increased with temperature, except possibly in the case of chromite brick, for which the value was nearly constant.

The thermal conductivities of some fire-clay, silica, and magnesia bricks were investigated by Dougill, Hodsdon, and Cobb. Their apparatus was somewhat similar to Wougléman's, but designed to take ordinary sized samples. The heat transmitted was measured by the evaporation of water from a vessel connected to the top surface of the brick. This calorimeter was composed of a large vessel, 9 inches long by 4 1/2 with by 3 inches high, with a piano base. Within the larger vessel was fixed the calorimeter proper, consisting of a chamber 4 inches long by 2 inches wide by 2 1/2 inches high. Steam distilling from this inner vessel passed through a sloping tube to a condenser, the water being collected in a measuring jar.

The usual rate of evaporation was about 5 c.c. per minute. The authors state that it was found advantageous to surround the inner chamber with a non-conducting jacket, and for this purpose sheet rubber was found to be satisfactory.

Probably it would be better if, in this method, the calorimeter was entirely separated from metallic connection with the larger vessel, since the existence of a slight gradient of temperature across the metal base might seriously vitiate the results.

An interesting fact brought out by the investigation is the marked decrease with temperature in the thermal conductivity of magnesia brick.

(c) Boyd Dudley.—Experiments on fire-clay, silica, and magnesia bricks of American manufacture were carried out by Boyd Dudley. The material under test consisted of a wall of a furnace heated by means of by-product coke. By careful regulation of the draught a uniform combustion through a depth of 26 inches was obtained. The bricks composing the wall were 9 inches by 4 1/2 inches, and built so as to produce a flat surface. The heat transmitted through a definite area of the wall was measured by a flow calorimeter 8 inches by 8 inches, fitted with a guard-ring. A period from eight to nine hours was allowed to elapse after starting the fire before observations were commenced.

The temperature gradient through the bricks was obtained by means of a platinum, platinum-rhodium couple inserted to various depths in holes bored to within 1/2 inch of the inner face, measurements being made every 1/2 inch to within 1/10 inch of the cold face.

This method of ascertaining the temperate at various points is simple, but suffers from the disadvantage that the couple wires are perpendicular to the isothermal planes and the readings may be vitiated by conduction along the wires sending the junction.

Dudley found that the conductivity of magnesite was practically constant between 445° and 830°; which is contrary to the results of Dougill, Hodsdon, and Cobb.

(d) Griffiths.—An apparatus used by Griffiths for measuring the conductivity of slabs of refractory materials is illustrated in Fig. 11. The faces of these materials are always irregular and are generally slightly curved.

2 Trans. Forestry Soc., 1917, xii. 106.
so that it is difficult to obtain a uniform surface temperature. With a view to meeting the difficulty the heat was transmitted to the hot face of the brick by means of molten metal, which adapts itself to the irregularities of the surface. Tin was found to be satisfactory for the purpose at low temperatures. It was contained in the cast-iron tray T, which has a uniformly distributed heating coil attached to its under surface. The depth of the molten metal is about 1 cm., and the brick under test rests on three projections, so that the free surface of the tin around the edges stands at a level of about 2 mm. above the immersed surface of the brick.

The temperature of the molten tin was obtained by means of a platinum-platinum-iridium couple. The details of the construction of this couple are shown in Fig. 12. The wires were separately insulated in the quartz tubes, which are enclosed in an outer sheath, the external diameter of which was approximately 8 mm. The bulb B was sealed off in the oxy-acetylene blowpipe after the insertion of the wires, and no difficulty was found in heading the tube into the T-form with the wires in situ, provided the heating was not unduly prolonged. By rotating the couple the temperature distribution over a wide area could be explored, and the insulation of the quartz was sufficiently good to prevent any leakage from the heating circuit into the potentiometer.

The temperature of the cold surface of the brick was determined by several iron-constantan (constantan) thermocouples bedded just flush with the surface. The calorimeter was attached to this surface by means of a thin layer of Paraffin wax cement.

The construction of the flow calorimeter will be understood from Fig. 11. The guard-ring G is separated from the calorimeter proper C by a narrow gap about 1 mm. wide, the space being filled with nice plates M set on edge so as to produce a level surface. The inflowing water divides at D, and flows through adjacent turns of piping in the calorimeter and the guard-ring. Since the temperatures of the two streams are the same, this tends to eliminate any gradient of temperature across the gap separating the calorimeter from the guard-ring. The ratio of flow was adjusted to produce equal temperature rise. Differential couples of six pairs of copper-constantan measured the rise in temperature in the water flowing through the calorimeter. The tube containing the inflowing couple is separated from metallic contact with the calorimeter by a short connecting piece of ebonite B. A steady stream of water is obtained by the constant-level tank shown, and the rate of flow through the calorimeter determined by the time required to collect one litre of water.

In order to detect any systematic errors the experimental conditions were varied by altering the rate of flow, changing the differential couples, and the thickness of slab experimented on.

In experiments at temperatures above 450° the hot face was maintained at a uniform temperature by pressing it against a flat iron plate forming a portion of the wall of a large uniformly heated muffle. In this case the hot-face temperature was determined by two bare nickel-copper, nickel-chromium couples of No. 19 gauge wire cemented on the surface.

Data for the same sample over the same temperature range obtained by two different modes of heating were in close agreement; the molten metal bath method giving more concordant results than the muffle method.

(e) Lesz.—Lesz has determined the conductivity of small thin slabs of material by means of a somewhat novel method. His arrangement is shown diagrammatically in Fig. 13. A small hot plate is formed of two copper discs C and U, between which is sandwiched a heating coil of platinum insulated by mica. The thickness of the coil with the insulation was .11 cm., the thickness of C .103 cm., and U .312. cm.

S was the substance whose conductivity was to be measured, while M was another copper disc .32 cm. thick. The contacts of S with U and M were improved by scoring the surface with glycerine and sliding them together. The diameter of all the discs was 4 cm. At opposite ends of a diameter of

each copper disc were soldered a platinum and copper wire which formed a thermojunction for the measurement of temperature.

When the discs had been assembled they were varnished to give them the same emissivity, and the pile was suspended in a constant temperature enclosure. The current was switched on in the heating coil, and after a due time had been allowed for the steady state to be reached, the energy was measured and the temperatures of the three copper discs.

The theory may be briefly stated as follows:

Let $H$ = rate of energy supplied to the heating coil,

$k$ = heat loss per second per sq. cm. for $1\,^\circ$ excess of temperature of the discs over that of the enclosure,

$e$ = the excess of temperature over that of the enclosure,

$t$ = thickness of disc,

$r$ = radius of the discs.

Now the heat received per second by the disc $M$ and given up to the air is

$$\pi r^2k \left(1 + \frac{2I}{r} \right) v_M t$$

Similarly the heat received by $N$ and given up to the air from its exposed surface or passed up to $M$ is

$$\pi r^2k \left(1 + \frac{2I}{r} \right) v_M t + \pi r^2k \frac{2I}{r} \left(\frac{v_M + v_N}{r} - \frac{v_M}{2} \right).$$

If $K$ is the thermal conductivity of the disc $N$, then the heat flowing through the disc is

$$\pi r^2K \left(\frac{v_M - v_N}{s} \right).$$

Assuming that the heat flowing through the disc is the mean of the heat flowing into and out of the disc, i.e. the mean of the first two quantities above, we get

$$K \left(\frac{v_M - v_N}{g} \right) = k \left( v_M + \frac{2}{r} \left( \frac{v_M - v_N}{4} \frac{v_M + v_N}{4} \right) \right).$$

Which gives us a relation between $K$ and $k$.

Further, the total heat imparted to the system must equal that given up to the air from all the exposed surfaces, and therefore we get the equation

$$H = \pi r^2 \left( v_M + v_N + \frac{2}{r} \left( f_M v_M + f_N v_N - \frac{v_M + v_N}{2} - t_0 v_0 \right) \right).$$

From these two equations the values of $K$ and $k$ can be determined by measuring $H$ and the temperatures of the discs.

Let us work out the correction for the conduction of heat along the thermocouple wires and the leads to the heating coil.

He used this method for determining the conductivity, and variation of conductivity with temperature, of a number of substances, such as glass, sulphur, bismuth, shellac, fibre, naphthalene, etc. He also extended this method to apply to liquids in the manner described below ($§$ 7 ii.).

$§$ 7. QiUdS: METALS ($K = 0.015$ to $1.00$).

The class of metals is distinguished by its high conductivity alike of heat and electricity. This is explained by the supposed dependence of the two phenomena on the diffusion of electrons, and a mathematical relationship has been established between them which, as will be shown below, is partially confirmed by experiment. In the non-metallic solid, on the other hand, the electron is supposed to be capable of vibration only, so that heat conduction is assumed to be due to internal rotation. While this theory explains the known facts better than any yet advanced, it should be pointed out that it fails to account for the fact that some dielectrics have a higher conductivity than the worse conducting metals, e.g. the conductivity of quartz parallel to the axis ($K = 0.029$) is greater than that of bismuth ($K = 0.018$ to $0.019$).

The conductivities of metals range from $0.015$ to $1.00$ C.G.S. units. Practically all the pure metals have a small negative coefficient of conductivity with rising temperature, while the alloys show a positive coefficient.

The high conducting power of metals gives rise to certain modifications in the types of apparatus described above. Thus it is necessary to use a considerable thickness of metal to obtain appreciable temperature gradients, and the measurement of the boundary temperatures is very difficult. This latter point is well illustrated by the early experiments in which a slab of metal was heated on one side by steam or hot water and cooled on the other side by ice or cold water. Under these conditions the temperatures of the faces of the metal were assumed to be those of the steam, ice, or water as the case may be. Acting on this assumption, Clement obtained a value for the conductivity of copper which was 200 times too low, while Defant, who was aware of the source of error in Clement's work, and took extraordinary precautions to secure efficient stirring, still obtained a value for copper which was about one-fifth of the true value. The difficulty is due to the fact that, even with the most vigorous stirring, there is always in contact with the metal surface a thin film of fluid which is at rest, and thus has a temperature gradient through it. If $h$ is the thickness of the metallic plate (of true conductivity $K$) and $d_1$ and $d_2$ of the stationary film of fluid (of conductivity $K_f$) on each side, it can easily be shown that the effect of assuming the temperatures of the metallic surfaces to be those of the moving liquid on such side
is to give an apparent conductivity of the metal equal to the true conductivity divided by

\[ 1 + \frac{K}{K'} \]

In the case of copper and water the value of \( K/K' \) is about 700, so that the value of \( d_1 \) and \( d_2 \) would only have to be \( \frac{1}{2} \) of the thickness of the copper to obtain an apparent conductivity one-fifth of its true value.

(i.) Plate Method. Hall.—In spite of the difficulties mentioned above, the plate method has been used—notably by Hall, to whom is due an ingenious method of determining the difference in temperature between the two faces of a thin metal plate. He experimented with a disc of iron 10 cm. in diameter and 2 cm. thick. Each side of the disc was coated with copper to a thickness of 2 mm. By attaching a copper wire to each side a differential thermometer was obtained the E.M.F. of which gave the difference in temperature between the two surfaces of the disc. Hall had a number of copper wires attached to the copper faces, which were immersed in streams of water at different temperatures. The heat coming through the disc was given by the rate of flow of the cold water (about 20 gm. per second) and the rise in temperature (about 0-5° C). The difference in temperature between the faces of the iron disc was of the order of 1°C, which corresponded to 10 microvolts of the differential couple. The individual wires gave readings differing by as much as 10 per cent, which was a serious source of uncertainty. Hall obtained values of conductivities as follows:

- Cast iron, 0-1400 C.G.S. units at 30°C, temperature coefficient = 0-00976.
- Pure iron, 0-1500 C.G.S. units at 30°C, temperature coefficient = 0-0093.

The value for pure iron is in good agreement with recent determinations, while the value for cast iron seems to be too high.

(ii.) Bar Methods.—For the reasons which have been indicated above, bars have been commonly adopted instead of plates for the purpose of conductivity measurements.

(a) Forbes.—One of the earliest methods of determining the conductivity of a metallic bar was that due to Forbes. He took a long bar kept at a fixed temperature at one end. When the steady state of heat flow had been reached, the temperature at a series of points was measured by means of mercury thermometers let into holes in the bar. By plotting these observations and drawing a smooth curve through them, the complete temperature distribution along the bar was determined. The tangent to the curve at any point gave the temperature gradient (slope) at that point.

To obtain the heat flowing across the particular cross-section of the bar, Forbes determined the total heat loss from the surface between this section and the end of the bar—the two quantities are obviously equal. For this purpose a separate experiment was made on a similar bar which was uniformly heated and left to cool in the same surroundings as the first bar. From the rate of cooling of this bar and a knowledge of its heat capacity, the rate of heat loss per unit area could be determined for any temperature. The data obtained were used for computing the heat loss from the surface of the first bar, measured from the particular cross-section. The temperature gradient having been determined in the first experiment, the conductivity was at once obtained.

Forbes used for the first experiment, which has been called the "static" experiment since it dealt with the steady state of heat flow, a bar of wrought iron 8 ft long and 1½ inch square section. The hot end of the bar was fixed into any iron crucible which was maintained at the temperature of melting lead or solder. The experimental conditions were varied by having the metal bright polished in one case and covered with white paper applied with a little paste in another case. The surface emissivity in the latter condition was eight times that in the former.

For the second or "dynamic" experiment in which the emissivity was determined for various temperatures, a bar of the same material and cross-section was used, but only 20 inches in length.

Forbes obtained the conductivity of wrought iron for a number of temperatures up to 200°C. He assumed, however, that the specific heat of iron was constant, whereas it increases by about 10 per cent for every 100°C rise. For this reason Forbes' values are obsolete. When corrected by Tait and Mitchell, they were brought more into line with modern values but were still unsatisfactory. Apparently another source of error arises from the fact that the "dynamic" experiment does not give the true emissivity coefficients applicable to the "static" experiment, owing to the temperature distribution inside the bar being different in two cases. This would not, however, account for the large discrepancies in the experiments, of which no satisfactory explanation has been given. Thus Forbes, using two bars respectively 1½-inch and 1-inch square section, obtained values differing by some 20 per cent, while Mitchell repeating the experiments on one bar and cooling it in the center obtained a value differing by 8 per cent.

In spite of the criticism that has been levelled at it, Forbes' experiment is interesting.
as being the first attempt to determine the conductivity of a metal in absolute measure. His method, which has been followed, with improvements, by a number of experimenters, notably Mitchell, Stewart, Lees, Calendar, and Nicholson. The last-mentioned made several important modifications in the method. To avoid uncertainties of surface loss, a large bar, 4 inches in diameter, was used and the loss from the bar was reduced by a quarter by lagging. The end of the bar, which was 4 feet long, was surrounded by a calorimeter and cooled by a stream of water. The rate of flow of the water and the temperature rise gave the quantity of heat passing out at the end of the bar. The heat leakage through the lagging could be computed and was only a small fraction of that absorbed by the calorimeter. The inaccuracies of Parry's method were much reduced by the above-mentioned modifications. The apparatus is illustrated in Fig. 14.

Griffiths has also made use of a similar method for measuring the conductivity of a series of aluminum alloys, intended for aeroplane engines, up to a temperature of 350°C. In his apparatus the heat was supplied by a nichrome strip wound on one end of a bar, while on the other end a spiral pipe was wound which acted as a flow calorimeter. The electrical input into the heating coil was found to equal the amount of heat flowing out through the calorimeter plus the amount lost laterally through the lagging, so that the thermal balance sheet was checked. Some of the results obtained by Griffiths are given in Table III.

**Note:** The values are approximate and subject to variations based on the specific conditions and materials used.
(b) Herget.—Herget made use of a guarding method for the purpose of determining the conductivity of a number of metals such as copper, iron, brass, mercury. The arrangement of the apparatus used for the mercury determination is shown in Fig. 15. A cylindrical column of mercury was contained in a glass tube AB, which was surrounded by an annular column of mercury which acted as a guard-ring. The surface of the mercury column was heated by steam, and the base of the outer column rested in an iron plate C which was cooled by ice. The tube carrying the central column of mercury projected through the iron plate into a brass ice calorimeter as shown. The temperature distribution was determined by means of four iron wires which projected into the central column. Each pair of these wires, with the intervening mercury, formed a differential iron-mercury couple which gave the difference in temperature between the ends of the two iron wires. The distribution of temperature was found to be linear when the steady state has been reached. The ice calorimeter gave the quantity of heat passing through the column, and thus the conductivity was obtained.

Herget’s value for mercury of 0.0201 is in close agreement with recent determinations such as that of Nettleton. Having obtained the value for mercury, he measured the conductivity of other metals by comparison. A column of mercury was superposed on a column of metal, each surrounded by a guard-ring, and from a comparison of the temperature gradients the conductivity was determined.

(c) Less.—Less determined the conductivity of a number of pure metals and alloys over a range of temperature from -180° C. to 30° C.

His apparatus is illustrated in Fig. 16.

It was a rod of metal 7 or 8 cm. long and about 0.5 cm. in diameter. The lower end fitted into a copper disc D, which formed the bottom of a copper cylinder T closed at the top. A, B, and C were three thin brass sleeves, fitting closely to the rod with which good thermal contact was secured by a film of olive oil. Of these A and B carried platinum cells for the measurement of temperature while C carried a heating coil of platinoid wire. The copper cylinder T was placed on a wire frame resting on the bottom of the Dewar flask V. Around the outside of T was wound a platinoid wire p of the same resistance as the heating coil C, and whenever the current was switched off from C it was switched on to p, so that the rate of heat supply to the apparatus as a whole was constant throughout the experiment. A further heating coil P wound on T enabled the temperature of the apparatus to be raised rapidly if desired.

The experiments were started at liquid-air temperature. The current was switched on to C until a suitable difference of resistance (generally equivalent to about 5° C.) was obtained between A and B. The current was then switched on to p, and after five or ten minutes the difference in resistance between the coils A and B was again measured, as well as the actual resistance of the lower end A. The difference in temperature between A and B when the heating current flowed round C, less the mean difference in temperature (before and after) when the current was flowing through p, gives the difference in temperature which would be produced if the heating current were continued in C and the surrounding tube T kept at a constant temperature, i.e. assuming the rate of rise of temperature of the apparatus was constant which was secured, as explained above.

Jour. de Phys., 1888, vii. 693.
While the general theory of the experiments was simple, they are remarkable for the skill and care with which Lecce explored the various sources of error. Thus the sleeves were of approximately equal length and size, and formulae were obtained giving the approximate effect of the dimensions of the sleeves and of the small differences in temperature between the rod and platinum resistance gauges on the sleeves. Again corrections were worked out for the effect of the leads in the heating coil C and the platinum cells A and B, while the fact that the observations did not apply strictly to the steady state of temperature distribution was shown to be of small effect.

Lecce's experiments over the range from -170° to 30° C., confirmed generally the conclusions of Jaeger and Desselhorst—from their work between 0° and 100° C.—that the pure metals show a slight decrease in conductivity with rise of temperature. He did not, however, find that the maximum conductivity always occurred at the lowest temperature. The electrical conductivity of the metal rods was also measured by Lecce, and his conclusions as to the relation between thermal and electrical conductivity will be referred to later (§ 10 i).

(iii) Electrical Methods.—Several methods for measuring the conductivity of a bar of metal have been proposed in which heat is supplied by passing an electric current through the bar itself. If the ends are kept at a constant temperature, there will be established throughout the bar a certain distribution of temperature, which will depend on the strength of the electric current, the electrical and thermal conductivity of the material, and the heat loss (if any) from the surface of the bar.

(a) Kohlrausch: Jaeger and Desselhorst.—Kohlrausch 1 took the case where all heat loss from the surface of the bar was prevented. Calling

\[ K = \text{thermal conductivity,} \]
\[ \lambda = \text{electrical conductivity,} \]
\[ \theta = \text{temperature at any point,} \]
\[ \nu = \text{electrical potential at any point,} \]

he obtained the following solution of the differential equations for thermal and electrical equilibrium:

\[ \theta = \frac{1}{2} \frac{\lambda \nu^2}{K} + A \theta + A', \]

where A and A' are constants. Hence, by determining the temperatures and potentials at three points, A and A' can be eliminated, and we get

\[ \frac{2K}{\lambda} = \frac{\partial (\theta_2 - \theta_1)}{\theta_2 - \theta_1} + \frac{\partial (\theta_3 - \theta_1)}{\theta_3 - \theta_1} + \frac{\partial (\nu_3 - \nu_1)}{\nu_3 - \nu_1}. \]

Kohlrausch also showed that if the conductor is of any shape, and is thermally and electrically insulated except for the two areas through which the current is supplied and through which heat is abstracted, the same solution holds. Hence, if holes are drilled in a bar for the purpose of inserting thermometers, the method will still be exact, provided that the temperatures and potentials are measured at the same points.

Jaeger and Desselhorst carried out Kohlrausch's method into practice. They took cylindrical bars of metal, 25 cm. long and generally about 2 cm. in diameter, with their ends fitted into copper blocks, which were screwed into large water-baths. The bar was surrounded by a cylindrical jacket, kept at a constant temperature by water or steam circulating outside it, the space between the bar and the jacket filled with wadding. There was, of course, a certain amount of heat loss through the wadding, which was estimated by varying the temperature of the jacket surrounding the bar. For the discussion of this and other corrections, reference must be made to the original paper. The temperatures were measured by thermocouples.

The determination of the temperatures and potentials at three points gives the ratio of the thermal and electrical conductivities, and the latter constant being easily determined, the thermal conductivity was obtained.

Jaeger and Desselhorst carried out a very extensive investigation on a number of pure metals and a few alloys for temperatures between 18° and 100° C. They found that pure metals, with one or two exceptions, showed a slight decrease of conductivity with increasing temperature, and that they obeyed approximately Lorentz's law—that the ratio of the thermal and electrical conductivities divided by the absolute temperature is a constant. Lorentz's constant showed a slight positive temperature coefficient.

Their work represents a most important contribution on the subject of conductivities, and their values have been amply confirmed by subsequent observers.

The method of Jaeger and Desselhorst has been used by Meissner 2 for measuring conductivities down to a temperature of 20° abs. His work confirmed generally the values of Lecce, but he found that both the resistivity \((1/K)\) and Lorentz's constant decreased rapidly as the temperature of liquid hydrogen was approached, showing a reduction at 20° abs. of about 85 per cent on the value at 0° C.

(b) Calender.—Calender 2 has also developed a method of determining the conductivity of a rod of metal which is heated by the passage of an electric current. The ends of the rod are kept at constant temperature by insertion into water-cooled copper blocks. The rod is

---

small change of resistance accurately, and of avoiding stray thermo-electric effects.

Duncan, using this method, found the conductivity of copper at 32° C. to be 1.007, which is about 8 per cent higher than that obtained by Jaeger and Desselhorst.

(c) Mendell and Angell.—Another example of an electrical method is that suggested by Mendell and, described in a paper by Angell, for measuring the conductivity of metals at high temperatures.

If a cylindrical rod is connected at its ends to two heavy electrodes and heated by a constant current, there will be a rising temperature gradient from the ends towards the middle of the rod. This longitudinal gradient will decrease as the middle is approached, and for an approachable distance on each side of the centre will be negligible. There will be an tendency, therefore, for the heat generated in this portion of the rod to flow towards the ends. The temperature gradients will be radial, and the heat will flow radially and be dissipated at the surface. Consider now a length of rod \( \ell \) within the central zone. Let \( r \) be the radius, \( K \) the fall of the potential per centimeter, \( I \) the current density (which is assumed uniform over the cross-section), \( \bar{\theta} \) and \( \bar{\theta} \), the temperatures at the axis and circumference respectively.

Then, since the heat generated within any cylindrical surface of radius \( r \) passes radially to the surface, we have

\[
\pi r^2 \ell J = 2 \pi r K \frac{d\theta}{dr}
\]

Integrating we get

\[
K = \frac{\pi \ell}{4(\bar{\theta} - \bar{\theta})^2}
\]

The above formula depends on the assumption that the current density is uniform over the cross-section. This is not strictly the case, since there is a temperature gradient from the axis to the circumference which gives rise to a variation of resistivity. Angell shows, however, that for metal rods of less than 2 cm. in diameter the effect of the variation is negligible. In the actual experiments a hollow cylinder was used, and the formula in this case is

\[
K = \frac{\pi \ell}{4(\bar{\theta} - \bar{\theta})^2} \left( \frac{r_1^2 - r_2^2}{2} - r_2 \log \frac{r_1}{r_2} \right)
\]

By measuring the dimensions of the cylinder, the values of \( K \) and \( I \), and the temperatures of the inner and outer surfaces, the value of \( K \) was obtained.

The apparatus used is illustrated in Fig. 17. The metallic rod was 1.2 cm. in diameter and about 15 cm. long. An inner hole was bored through the rod 0.17 cm. in diameter, and this was enlarged, as shown in the figure, except for the central length of 3 cm. The
resistance on one side of the central portion of the rod, while the other side was kept at a constant temperature. The method is an excellent one for determining the rate of the thermal conductivity of a metal, and will be used in the present investigation.

The method described in the paper is based on the determination of the thermal conductivity of a metal by means of a known temperature gradient. The temperature of the metal is determined by means of a known temperature gradient, and the rate of the thermal conductivity is determined by means of a known temperature gradient.

Further, it is shown that the thermal conductivity of the metal is determined by means of a known temperature gradient, and the rate of the thermal conductivity is determined by means of a known temperature gradient.

In the present work, the temperature of the metal is determined by means of a known temperature gradient, and the rate of the thermal conductivity is determined by means of a known temperature gradient.

For this purpose, a metal rod was cut into two halves, and the halves were placed in a vacuum chamber. The temperature of one half was maintained at 100°C, and the other half was maintained at 0°C. The rate of the thermal conductivity was determined by means of a known temperature gradient, and the rate of the thermal conductivity was determined by means of a known temperature gradient.

Further, it is shown that the thermal conductivity of the metal is determined by means of a known temperature gradient, and the rate of the thermal conductivity is determined by means of a known temperature gradient.

HEAT, CONDUCTION OF

found by Worthing. He also contends that the value of Lorenz's constant is of the order that would be expected from Jaeger and Düsselhout's value at 18° C., and the temperature coefficient which they found between 18° C. and 100° C. This was contrary to the very large change in the constant which Worthing found over the range 1200° C.

(iv) Indirect Methods.—In the case of metals it is often convenient to determine the conductivity by comparison with some other metal whose conductivity is known.

(a) Wiedemann and Franz.—As an example, the method of Wiedemann and Franz 1 may be quoted. These experimenters took a bar of metal, one end of which was maintained at a constant temperature, and which was submitted along its length to the effect of convection by radiation and conduction inside a constant temperature enclosure. When the steady flow of heat had been established, the temperatures at three points at equal distances apart were measured.

The temperature distribution along a bar under the conditions indicated is given by (cf. equation in § (b) (iii.) (b))

\[ KA \frac{d^{2} \theta}{dx^{2}} = E \theta \]

If now the temperatures \( \theta_1, \theta_2, \) and \( \theta_3 \) are measured at three equally spaced points at a distance \( a \) apart, it can be shown that

\[ a \sqrt{\frac{K \theta}{\lambda}} = \log (n \sqrt{n+1} - 1), \]

where

\[ n = \frac{\theta_3 - \theta_2}{\theta_2 - \theta_1} \]

So that if we take two bars of different materials, but with the same cross-section \( A \), the same perimeter \( p \), and the same coefficient of heat loss \( k \), and determine the temperatures in each case at three equally spaced points at the same distances apart, we get the ratio of conductivities from the following equation

\[ \sqrt{\frac{K_{1}}{K_{2}}} = \log \left( n + \sqrt{n^{2} - 1} \right) \]

The rods used by Wiedemann and Franz were half a meter long and 3 mm. in diameter, and in order to secure the same surface emissivity for all the rods, they were electropolished. One end of the rod was heated by steam and the remainder was surrounded by a water-cooled enclosure which could be exhausted if required. The temperatures at three equidistant points were measured by means of a sliding thermocouple.

Wiedemann and Franz drew up a table of relative conductivities of a number of metals. The experiments represented a considerable advance at the time they were carried out (nearly seventy years ago), but some of their results must now be regarded as absolute, the probable cause being the presence of impurities in their specimens.

There is also the point, to which Péclet drew attention so long ago as 1890, that the assumption of Newton's law of cooling, which only holds approximately for small differences of temperature, must introduce considerable error.

(b) Voigt.—Another method of comparing the conductivities of two metals is that due to Voigt. 2 He took thin plates of the two materials cut in the form of right-angled triangles, and placed them in contact along their hypotenuses. The lengths of the sides \( a \) and \( b \) (Fig. 18) are chosen so as to be approximately in proportion of the conductivities of the plates. Heat is then applied by means of a copper bar at 70° to 90° C. along the short side \( b \) of the good conductor or the long side \( a \) of the bad conductor. The whole surface of the composite plate was cooled with a layer of siliceous earth to which wax and tartaric acid are added. The acid melts at 45° C. and solidifies in crystals yielding a well-defined isothermal curve. The ratio of the conductivities is derived from measurements of the angles which the isothermal makes with the common hypotenuse, being in the proportion of the tangents of the angles. The limits of accuracy of which the method is capable is about 2 per cent.

Rinrsch 3 used this method for measuring the conductivity of copper containing varying amounts of phosphorus and arsenic. It has also been used for glasses.

(v) Periodic Flow Methods. (a) Augstren.—The method 4 is of interest in that it differs in principle from those previously described which have all been concerned with the steady state of heat flow. In this case the conductivity is deduced from observation of the periodic flow of heat in a long bar.

If we consider any thin cross-section of a rod the temperature of which is changing, the difference between the heat flowing into and out of this section must be equal to the heat lost from the surface of the section plus the heat required to raise the temperature of the section itself. So that we have (cf. § (b) (iii.) (b))

\[ KA \frac{d^{2} \theta}{dx^{2}} = E \theta + \frac{dQ}{dt}. \]

If the rod is surrounded by a guard-ring which prevents heat loss from the surface,

---

1 Ann. de Chimie, 1854, 11th 107.
3 Phys. Mag., 1893, xxi. 135.
Again, taking two points, each pair of the terms of the above expression leads to an independent value of $h^2$.

$$h^2 = \frac{\alpha^2}{\frac{T}{\Delta T} - \alpha^2} \frac{\ln \frac{\Delta T}{\Delta T'}}{\ln \frac{\alpha T}{\alpha T'}}$$

In practice these series may be limited to the first three or four terms as the coefficients $\Delta T, \alpha, \alpha'$, etc., rapidly diminish.

In Ångström's experiments a small section of a bar was enclosed and was submitted alternately to heating and cooling by steam and cold water respectively. The periods of heating and cooling were 12 minutes each, and when they had been continued for some time, the temperatures at each point of the bar became steadily periodic. Mercury thermometers were let into the bar at intervals of 5 cm. for temperature readings.

Ångström used for his first experiments bars 57 cm. long and of 2.4 cm. square section, while for some subsequent experiments he used a bar 118 cm. long and 3.5 cm. thick. His values for the conductivity of copper and iron at 50° C. were

<table>

</tr>
<tr>
<td>Iron</td>
<td>0.013</td>
<td>0.002 (1 - 0.002146)</td>
</tr>
</tbody>
</table>

The values obtained in the second experiments are much higher than those now accepted. The negative sign of the coefficient is confirmed by the work of Jüger and Dësschold and of Levès though the magnitudes are different.

Callendar has applied Ångström's method to the apparatus illustrated in Fig. 14. He varied the pressure of the steam in the heater so as to produce approximately simple harmonic oscillations, using periods of 60, 90, and 120 minutes. Callendar found a value for cast iron at 54° C. of 0.1141 (1 - 0.040069), which is in close agreement with modern values obtained by other methods.

There is no doubt that Ångström's method gives satisfactory results if due precautions are taken. It involves, however, the taking of large numbers of observations and their analysis may be very laborious.

(2) King.—A method resembling that of Ångström is due to King. His apparatus is shown diagrammatically in Fig. 20. A is a wire whose conductivity is to be determined and which is 2.5 mm. in diameter and about 40 cm. long. One end of the wire projects into a heating coil $K$ through which flows a periodic current following a sine law. At
two points of the wire are attached the thermocouples T, T, each connected to a short period galvanometer. In each thermocouple circuit is a counter E.M.F. which can be adjusted to balance the thermocouple E.M.F. at its mean value. The lag between the movements of the two galvano-

meters gives the velocity of propagation of the waves. If experiments are made with the waves of two periods \( t_1 \) and \( t_2 \) and the velocities are found to be \( v_1 \) and \( v_2 \), then it can be shown that the diffusivity \( k^2 \) is given by

\[
\frac{k^2}{t_1 t_2} = \frac{1}{4} \sqrt{\frac{(\nu_1^2 - \nu_2^2)}{\nu_1^2 + \nu_2^2}}
\]

King carried out experiments with waves of periods of 2 minutes and 5 minutes respectively, and he found values for the conductivity of copper and tin which are in close agreement with those of Jünger and Diesselhorst.

§ 1.4 SOLIDS: CRYSTALLINE AND AMORPHOUS.—In considering the various classes of solids which have been referred to above, it has been assumed that they have been symmetrical as regards the conductivity of heat. Some substances, however, owing to peculiarities of structure, give different values of conductivity in different directions. Thus Türling found that, in the case of wood, the conductivity was highest along the fibre and lowest in the direction perpendicular to the fibre and the lignous layers. As giving some idea of the magnitude of the differences some of his values are quoted in the following table. The figures are only comparative:

Similarly in the case of laminated rocks, such as slates and sandstones, Janetzko has shown that the conductivity is highest parallel to the cleavage.

Where such substances can be obtained in sufficient bulk their conductivities can be determined by one of the methods already described. In the case of small objects, however, such as crystals, which often show a marked asymmetry of heat flow, different methods have to be adopted.

(i.) De Saemarm.—The first to make a comprehensive study of crystalline conduction was de Saemarm. His method consisted in casting a thin plate out from a crystal with a film of white wax and applying heat at a point near the centre. As the plate becomes warm the wax melted and the point and the inequalities in conduction in different directions were indicated by the shape of the bounding line of melted wax. The curve in the case of an isotropic substance, such as glass or crystals of the cubic system, was always circular. In the rhombical system, with one axis of symmetry, the plate was perpendicular to the axis gave circles while any section parallel to the axis gave an ellipse. This is illustrated in Fig. 21, which gives the curves for a quartz crystal cut perpendicular and parallel to the main axis. Here the isothermal surface due to a point source in the crystal would be an ellipsoid of revolution about the main axis. The rule was found to be general in the rhombic and crystallographic axes coinciding.

In de Saemarm's experiments the heat was supplied by a wire or tube fitted into a hole bored in the plate of crystal, or the sun's rays were concentrated on a point by means of a lens. The values obtained were comparative, a circle indicating the plane in which the conduction was the same in all directions, while for an ellipse it could be shown that the conductivities along the axes were proportional to the square of their lengths.

(ii.) Lec.,—A method of determining the absolute values of thermal conductivities of crystals was suggested by Lec., and carried out by Lec.. A thin slice of the crystal was placed in contact with the ends of two bars of metal with their lengths in the same straight line, thus forming a composite bar. Brass was chosen because it readily amalgamates with mercury, and the amalgamated surfaces were found to give extremely good thermal contact with the crystal. The bar was packed in sawdust, and one end was heated by steam and the other immersed in cold water. The temperature distribution was obtained by a series of thermocouples attached to the bar, and from this the temperatures of the two

1 *Phil. Mag.*, 4th series, v. and vi.
2 *Journ. de Phys.* v. 150.

---

\[ \text{Journ. de Phys.} ^{\text{v.} 150} \]
faces of the crystal plate could be deduced after making a small correction for the layer of mercury as determined in a separate experiment. The amount of heat passing along the bar and through the crystal was calculated from a knowledge of the absolute conductivity of the bar, which was obtained by an improved Forbes method.

Lees found that for quartz the conductivity parallel to the optic axis was \(0.0239\) and perpendicular to the axis \(0.0138\).

§ (7) Liquids \((K = 0.0003\) to \(0.0015\)).—The problem of determining the conductivity of a liquid is complicated by the ease with which convection currents are set up in any mass of fluid with a temperature gradient through it. Thus if the liquid at any point is at a higher temperature than the surrounding liquid, it will have a lower density, owing to its expansion with temperature, and will, if below the surface, tend to rise. Should the temperature difference be maintained at the particular point, a continuous current will be established. The laws governing such convection currents are very complicated, and the heat conveyed by them is often large as compared with the amount passing through the liquid by pure conduction or diffusion. In attempting, therefore, to determine the conductivity of the liquid the plan is commonly adopted of eliminating convection. This may be accomplished by taking a column of liquid, supplying heat at a horizontal surface at the top of the liquid, and abstracting heat at a horizontal surface at the bottom of the liquid; or by taking a film of liquid so thin that, independent of its orientation, the transfer of heat by convection is negligible. An alternative method is to regulate the heat loss by convection so that it takes place under well-defined and measurable conditions. Thus, when a liquid is made to flow with a streamine motion through a heated tube, a relation can be established between the heat carried off by this forced convection, and the temperature gradients and conductivity in the liquid. Examples of methods applying these principles are described below.

(1) *Column Method*. (a) *Berge*.—The apparatus used by Berge for determining the conductivity of a column of mercury surrounded by a guard-ring has already been described in § (6) (ii.) (b). It will be noted that the heat is here supplied at the top of the liquid, and flows down through the liquid to the bottom, which is cooled.

(b) *K. Weber*.—He used a similar method, supplying the heat to the top of a column of liquid from a vessel kept at a certain temperature by oil electrically heated, while the bottom of the column was cooled by a horizontal copper plate standing in ice. The temperature difference was taken at two points, \(1\) cm. apart, by means of copper-constantan couples. His values are included in Table IV.

(c) *Chree*.—He experimented with liquids heated on the surface, and determined the diffusivity by observations of the variable state. He took a cylindrical container \(10\) cm. in diameter into which liquid was poured to a depth of \(5-2\) cm. A hat-bottomed dish, \(10\) cm. in diameter, rested on the surface of the liquid, while a fine platinum wire \(64\) cm. long was attached in a horizontal position \(2-0\) cm. below the surface. This wire, to which were attached copper leads, served as a resistance thermometer. Hot water was poured into the dish, and the rate at which the heat passed through the dish into the liquid below could be obtained from observations of the fall in temperature of the water in the dish after making a correction, obtained by an independent experiment, of the heat lost from the surface of the water. The temperature of the water was initially about \(75^\circ\), and immediately after it had been poured into the dish, a temperature rise was indicated by the platinum thermometer, which then remained stationary for several minutes. After this period the thermometer began to rise rapidly, and continued to rise at a decreasing rate towards its maximum, which was not reached for several hours. Chree took temperature time observations, and obtained the point at which the temperature rise was at maximum rate, generally about ten minutes after the start.

*Theory* shows that if it were possible suddenly to apply a quantity of heat to the surface of the liquid, the time of maximum rise would be given by

\[t = 0.0172^{x^2};\]

*being the distance of the point below the surface, and \(\rho, c, \text{and } K\) being the density, specific heat, and conductivity of the liquid.

The conditions of the actual experiments were different in that the heat was applied at a decreasing rate for an appreciable time, and Chree gives the mathematical expression applicable to this case. It is interesting to note that in some experiments the water was allowed to remain in the dish for the duration of the experiment, while in others it was syphoned off shortly after pouring into the dish. The results obtained give a very fair agreement, and confirm the correctness of Careé's formula.

The values for the conductivity of water is supported by the more recent determinations by other methods.

(ii.) *Film Method*.—(a) *Lees*.—measured the

\[\text{Phil. Trans. Roy. Soc., 1908, excl. 418.}\]
experiment was made to determine it having air instead of liquid between M and L. The heat flowing through the liquid was then obtained, and this with the difference in temperature between M and L gave the conductivity of the liquid.

The film of liquid was horizontal in the experiments, and the heating was from the top surface so that convection was eliminated. It is interesting to note that when the apparatus was tilted through 15° the apparent conductivity only increased 1 per cent.

Lees determined the conductivity of water, glycerine, ethyl alcohol, and methyl alcohol, and his values are in close agreement with those of Weber.

Lees also investigated the conductivity of mixtures of water with varying amounts of glycerine, methyl alcohol, ethyl alcohol, nitric acid, sugar, and attempted to connect the conductivity of the mixture with that of the constituents. Plotting percentage composition by weight against conductivity he found that no general law could be deduced. If, however, percentages of volume were taken, similar curves were obtained which gave a conductivity somewhat less than that given by a linear formula.

\[ K_1v_1 + K_2v_2 = K \]

The value was also greater than that calculated assuming a linear formula of resistivity (i.e. reciprocal of conductivity). The latter formula is, however, closer to the experimental results than that based on a linear law of conductivity. Lees then obtained a closer approximation for the resistivity formula based on the probable distribution of the molecules of the two substances. From the agreement with experiment he deduces that the thermal conductivity of a substance is not greatly affected when it enters as one constituent into a physical mixture, and that the conductivity of the mixture depends directly on the amounts and conductivities of its constituents. He also experimented with mixtures of hard with varying amounts of finely divided iron, marble, zinc sulphide, and sugar, and found that the same conclusions hold.

Lees made further use of the apparatus described above to investigate any change of conductivity on melting. He found that in the case of the substances naphthaline, paraffin oil, and sodium hydrogen phosphate (NaH₂PO₄·12H₂O) there was no discontinuity at the melting-point, and that the conductivity decreased with rise of temperature both in the liquid and solid state. A decrease of 20 per cent in conductivity was found in the case of calcium chloride (CaCl₂·2H₂O) at the melting-point; but owing to its affinity for water the results were not so reliable as for the other substances. It is interesting to note that Barnes² found a decrease of 16 per cent in the case of thymol at the melting-point (125° C).

(6) Goldschmidt² adapted the "hot-wire" method as used for gases (see § 8 (ii) below). The liquid was contained in a tube only 3 mm in diameter, and it is stated that convection was eliminated.

(66) Flow Methods.—The first observer to use a flow method for measuring the conductivity of a liquid appears to have been Gnielinski,¹ but his method is not described here, as those of Callender and of Nettleton seem to be preferable.

(a) Callender.¹—Consider a long metal tube heated electrically and with a continuous stream of liquid passing through it. Let K be the conductivity of the liquid, r the specific heat per unit volume, v the velocity, and θ the temperature at a distance x from the axis of the tube, and let x be the distance measured along the tube. Then, assuming that the flow of the liquid is linear and neglecting the minute effect of longitudinal conduction, it is obvious that the heat carried off by the liquid flowing through any thin ring in a cross-section of the tube will be equal to the difference between the heat passing into and out of the ring by conduction. This gives the equation:

\[ \frac{d}{dx}\left(\frac{K_0}{r_0}\vartheta\right) = \pi r_0^2 \frac{dv}{dx} \]

The solution of this equation will be much simplified if we can assume that the longitudinal gradient \( \frac{d\vartheta}{dx} \) is constant over the cross-section of the tube at any point and is equal to \( \vartheta' \), where \( \vartheta' \) is the rise of temperature observed in a length l. This will not be true near the inflow end of the tube, where the radial distribution of temperature is rapidly changing, but it will very likely represent the limiting state, which is attained when the liquid has flowed along the tube for some distance. Further, the quantity \( \frac{dv}{dx} \) in the equation above is a function of \( x \) and of the viscosity which can be taken as constant for the small temperature changes met with in the experiment. The velocity at any point is then given by:

\[ v = V \left(1 - \frac{r}{r_0}\right) \]

where V is the mean velocity, Q the flow in c.c. per second, and \( r_0 \) the internal radius of the tube.

Substituting and integrating from the temperature \( \vartheta_0 \) of the surface of the tube, we find:

\[ \vartheta - \vartheta_0 = \frac{Q' r}{2nK} \left( r^2 - \frac{r_0^2}{r} \right) \]

¹ Stil. J. 139, 1892, xiv. 1.
The temperature \( \theta_1 \) at the axis of the tube, where \( r = 0 \), is given by

\[
\theta_1 = \frac{3Q\rho}{8\pi r K}.
\]

The mean temperature \( \theta_m \) of the flow, allowing for variation of velocity over the cross-section, is given by

\[
\theta_m = \frac{11Q\rho}{4\pi r K}.
\]

For the purposes of his experiment, Callendar took a platinum tube through which a current was passed. By measuring the resistance of consecutive sections of the tube, he was able to obtain the value of the gradient \( \frac{\partial \rho}{\partial r} \), as well as the value of \( \theta_1 \) at any section, \( \theta_2 \) appears to have been measured at the end of the platinum tube, and the value of \( \rho_0 \) or the mean temperature of the cross-section of flow at that point, was obtained by ensuring good mixing of the liquid as it left the platinum tube, its temperature being taken by means of a platinum thermometer. These quantities, together with the measurement of the rate of flow, gave the conductivity.

The device used by Callendar for obtaining a constant rise of temperature along the platinum tube is noteworthy. Thus, if \( R_p \) is the resistance per cm. of the platinum tube at the initial temperature, \( \alpha \) its temperature coefficient of resistance, and if \( K \) is the conductivity of the tube, \( \rho \) its resistance, \( A \) its cross-section, and \( Q \) is the rate of flow of liquid, then we have

\[
(\frac{dR}{R})_p = \frac{Q\rho}{\alpha dA} + E\frac{d\rho}{\rho}.
\]

If now \( (dR/R)_p \) is made equal to \( R_p \), the gradient \( d\rho/\rho \) will be constant. By choosing suitable dimensions for the diameter and wall thickness of the platinum tube it is possible to secure the above condition.

Callendar does not give the full experimental details, but the method seems very promising. It possesses advantages over the film method in that it avoids the difficulty of measuring accurately the thickness of the film, and requires no correction for radiation through the liquid, since all the heat lost by the inner surface of the tube must be absorbed by the liquid itself.

(b) Nettleton.--An ingenious method for determining the conductivity of mercury is due to Nettleton. A slow stream of mercury is forced up a vertical glass tube, of which the top is steam-jacketed, the bottom ended in ice, and the middle portion surrounds by a constant temperature enclosure. At one point the temperature of the column of mercury will be the same as that of the enclosure, which is taken as the zero of reference. If now \( \theta_1 \) and \( \theta_2 \) are the temperatures at distances 1/2 above and below this point, it can be shown that

\[
\frac{\theta_1 - \theta_2}{\theta_2} = \frac{\alpha \rho_0}{\pi},
\]

s being the specific heat of mercury, \( \alpha \) the number of grams per second, and \( A \) the cross-sectional area of the tube. From the above equation the conductivity is easily obtained.

For full particulars of the method, reference must be made to Nettleton's original papers.\(^1\)

\(^1\) Ann. Nat., 1873, 1, 947.

§ 8. Gases (\( K = 0.000015 \) to 0.000026).--As in the case of liquids, the determination of the conductivity of a gas is complicated by convection and radiation effects. The attempt is generally made to eliminate the former and apply a correction for the latter. A number of observers have investigated the problem, and their methods fall into three classes, viz., the cooling thermometer method, the hot-wire method, and the film method.

(i) Cooling Thermometer Method. Knudt and Warburg.\(^2\)--These observers investigated the rate of cooling of a thermometer, the bulb of which was in an enclosure filled with the gas under experiment. They found that for air the rate of cooling remained constant for pressures between 150 mm. and 1 mm., and for hydrogen, between 150 mm. and 9 mm.

It was therefore concluded that within these limits the action of convection currents was negligible, and that the heat loss took place by conduction through the gas and by radiation, after allowing a time correction for the conduction along the thermometer stem. To determine the radiation loss, the enclosure was exhausted as completely as possible, and the rate of cooling was then found to be independent of the shape of the enclosure. This showed that the effect of conduction through any residual gas was negligible.

The radiation being thus known, the cooling due to conduction was obtained by difference. If the thermal capacity of the thermometer is measured, the absolute value of the conductivity of the gas could be deduced.

Knudt and Warburg found that the conductivity of hydrogen was seven times that of air, which was in accordance with Maxwell's prediction. Their value for air at 0°C was 0.0000402.

Stefan\(^3\) adopted a similar method, taking two coaxial cylinders of thin copper with the gas to be tested between them. The inner cylinder served as an air thermometer, its tube passing through the outer cylinder and dipping into a vessel of water. Observing the rate of cooling of the thermometer, Stefan obtained the value for \( K_o \) of 0.0000533 for the conductivity of air.

A value very close to this was obtained by Winkeldorff,\(^4\) who experimented with spheres and cylinders on the same lines as Stefan.

\(^3\) Journ. de Phys., 1873, 11, 147.

(ii) Hot-wire Method. Schliefermacher.—

Originally due to Andrews, this method was used by Schliefermacher for measuring the heat conductivity of a gas. An electrically heated wire is surrounded by a coaxial cylinder containing the gas under experiment. The procedure is very similar to that explained above, except that the wire is kept at a constant temperature, and the rate of energy dissipation is measured. As before, the vessel is exhausted so as to obtain the radiation losses and the end corrections.

The hot-wire method has been adopted by a number of observers, and some of their values for the conductivity of air at 0°C are given below:

<table>

The latest exponent was Weber. He used a glass tube about 2.6 cm in diameter with a platinum wire 12 cm long stretched down the axis. The temperature of the wire varied from 7°C to 25°C above the surroundings. Particular attention was paid to the question of convection by studying the heat loss from the wire in the horizontal and vertical positions, and for pressures from atmospheric down to a few millimeters. The end effect was determined by experiment with two vessels similar in all respects except their length. For further particulars of the various corrections, reference should be made to the original paper.

(iii) Film Methods.—As in the case of liquids, a thin horizontal film, with the upper surface kept at a higher temperature than the lower, has been used to eliminate convection.

(a) Todd.—Acting on a suggestion made by Paynting, Todd adopted the film method. The heat transfer across the film being by conduction and radiation and the latter being independent of the thickness, it was possible, by experimenting on layers of different thicknesses, to eliminate the radiation loss.

The apparatus consisted of a plate 30 cm in diameter, heated by steam in its top surface. The film of air was contained between this plate and a similar plate, which formed the top of a flow calorimeter. The air film was isolated from the surrounding air by a double-walled cylinder of paper, which fitted the two discs closely. The heat reaching the cold plate was obtained from the flow calorimeter in the usual way, while the temperatures of the steam and water in contact with the plates was measured. An appropriate correction was made for the difference in temperature between the steam and water and the respective plates. Todd experimented on films from 1 mm to 5 mm in thickness, and obtained a value for the conductivity of air at 35°C, of 0.0000937, which is equivalent to 0.0000905 at 0°C.

It would perhaps have been better if it had been possible to provide the calorimeter with a guard-ring and improve its thermal insulation.

(b) Herce and Lamy.—These experiments were also made use of a film of gas heated on its upper surface. The arrangement of the apparatus is shown diagrammatically in Fig. 23. B is a hot plate surrounded by a guard-ring. C is a water-cooled plate. The function of the plate A is to prevent any heat loss from the upper surface of B, so that all the heat generated in B would pass through the air film to C. For this purpose, A was maintained at the same temperature as B.

All the plates were of copper. A, B, and D each consisted of two sheets of copper clamped together, and enclosing a heating coil of manganin and some thermocouple wires. The latter consisted of silver-covered constantan, which was bent into grooves in the plates and insulated by a wax of high melting-point. The constantan wires formed couples with the copper plates and return copper leads. The plate B was supported from D by three L-shaped ivory buttons. The surfaces of B and C, which faced each other, were ground true and silver-plated, and extraordinary care was taken to obtain the mean distance between the plates of careful maintaining. The apparatus was made air-tight by a ring of stout rubber clamped to A and C by steel tapes.

The plates were held together near the outer edge by three bolts passing through glass distance pieces.

When making an experiment the temperatures of the plates A, B, and D were adjusted to be approximately equal, corrections being made for the heat transferred due to small differences of temperature. The plate A was always kept slightly hotter than B, so as to avoid any possibility of convection currents. The radiation correction was determined by independent experiments on a silvered dome flask. It would have been preferable if it had been possible to determine it on the apparatus itself, but the point is not of importance.
since the correction amounted to less than 2 per cent.

The thickness of the air-film used was 6.28 mm., and there was a difference of temperature of 20° C. between the plates. The conductivity of air at 0° C. was found to be 0.000540.

§ (9) Discussion of Methods.—It will be realised from the experiments which have been described above that thermal conductivity is among the more difficult of the physical constants to measure with any degree of precision. When compared, for example, with electrical conductivity, it is noticed that there is nothing corresponding to an "insulator" in the electrical sense, which would enable the heat flow to be easily directed into any desired channel; while the almost instantaneous equilibrium established in an electrical system finds no thermal counterpart. Nevertheless, the divergencies in the values obtained by different experimenters for the same material are often rather surprising. Such divergencies, which are not infrequently of the order of 20 per cent., could probably be minimised by the observance of due precautions. An attempt is made below to set out some of the more obvious of these.

As has been already shown, the determination of absolute conductivity involves the measurement of three quantities, viz. the energy supplied to or passing through a body, the temperature distribution, and the dimensions of the body.

(i.) Energy Measurement.—Dealing first with the measurement of energy, the advantages of electrical supply are obvious. It is applicable over a wide range of temperature, it is easy to distribute uniformly, and it presents few difficulties of measurement. Further, the conversion from electrical to thermal units can now be accomplished with considerable precision, in view of the substantial agreement to the value of the mechanical equivalent of heat.

When an enclosure of any size is to be heated electrically, it is convenient to blow air over a bare resistor element, as was done by Lamb and Wilson, while baffle plates can be used with advantage for the purpose of shielding the walls from radiation and of directing the air flow. When a flat heater is required, care should be taken to secure uniform winding of the resistor, which should be clamped between metal plates, so as to give a flat surface and to reduce inequalities of temperature distribution. For this latter purpose, thin plates of copper or aluminium are useful, owing to their high conductivity. If the hot plate is surrounded by a guard-ring, there should be no metallic contact between the two, and the guard-ring heater should be capable of independent adjustment. Except in the case of short resistor elements, such as those of Niven and Poole, the escape of heat by conduction along the leads is not important, but if any correction is to be applied, reference may be made to the method of Lees.

When the body itself is used as a resistor, as with the so-called "electrical method," applicable to metals, the heavy currents and small potential drops make the energy measurement more difficult (see, for example, Angel's method). It is sometimes desirable to use alternating current to avoid Peltier effects, and the Thomson effect has also to be considered.

An alternative to measuring the electrical energy supplied is to determine the heat passing out of the body. This can be done by the usual devices of calorimetry, such as measuring the ice melted or the water evaporated in a certain time, or, more satisfactorily, by means of a flow calorimeter. Examples of the last-mentioned are seen in Figs. 11 and 14. Several important precautions have to be observed with this instrument. The tank for supplying water should be kept at a constant level and temperature. At the in-flow or out-flow points, where the temperature are taken, provision should be made for securing thorough mixing of the water so that the mean temperature of the stream may be recorded in each case. This can be done conveniently by means of baffles or plugs of wire gauze inserted in the flow tubes. A metallic pipe, preferably of copper, should be used for conveying the stream inside the calorimeter, but, both at the inflow and outflow, there should be a break in the pipe so as to prevent conduction losses along the metal. For this purpose rubber or enameled connecting pieces can be used. The rise in temperature between the in-flow and out-flow can be measured best by a differential arrangement of resistance thermometers or a series of thermocouples.

(ii.) Temperature Measurement.—One of the main difficulties met with in conductivity experiments is the measurement of surface temperatures. Attention has already been drawn to the point in the case of metallic surfaces in contact with well-stirred liquids, and it has been shown that enormous errors may occur through assuming that the temperature of the metal surface is that of the mass of the liquid. Similarly in the case of two solid surfaces which are nominally in contact, there will often be a sharp temperature discontinuity due to the interposition of air gaps. The fact is of great importance where the conductivity of the solid, whose surface temperature is desired, is at all comparable with that of air. Thus, in the case of insulating materials, an appreciable error is introduced by assuming the temperature of the metal plate which forms the boundary of the...
material in that of the surface of the material itself. More care must, however, be taken in the case of materials of medium conductivity. By using small specimens with good surfaces and improving the thermal contact with a glycerine or mercury film, Less succeeded in surmounting the difficulty, but if such methods are impracticable it is better to abandon the attempt to determine surface temperature and measure the temperature of isothermal planes within the material. This procedure was adopted by a number of experimenters, e.g. Nusselt, Niven, Poude, and Dougill, Hossman, and Cobb. Coming to metals, the method of Hall for measuring surface temperatures has much to commend it. At higher temperatures, where surface conductivity becomes an important factor, the device of Angell is interesting and appears to have been successful. However, the difficulties of determining the surface temperature of a metal by any contact method are so great that, wherever possible, the temperature should be measured at isothermal surfaces within the metal, which will generally be in the form of a bar.

Another important point affecting temperature measurements is to ensure that the thermal equilibrium has been reached before the final readings are taken. With materials of high diffusivity, such as metals, equilibrium is quickly established, but the process is very slow in the case of insulating materials. If the initial temperature of the material is known, its approximate diffusivity, and the boundary temperatures to which it is to be subjected, it is possible to estimate the time required for equilibrium. A calculation of this kind has been given by Niven for a cylinder of sand heated axially. This procedure is not to be generally recommended, as, apart from the difficulty of such calculations, the degree to which the diffusivities of insulating materials is very meagre owing to the fact that the specific heat cannot readily be measured.

The matter, however, can be tested experimentally. Taking, for example, the case in which the temperature of the bulk of the material has to be raised, it will be found that a measurement of the energy supplied to maintain a constant difference in temperature will give an apparent conductivity which will decrease as time elapses, gradually approaching a steady value corresponding to the condition of equilibrium.

As an instrument for measuring temperature distribution the thermocouple is the most generally useful. When employing it, care should always be taken to keep the wires leading from the junction in the isothermal planes for an appreciable distance. Otherwise, as Nusselt has shown, very large errors may occur.

(iii) Dimensions and Shape.—The measure-
A measure of the absolute temperature. On the development of the electrostatic theory of atoms, and more
recently H. A. Lorenz, applying the kinetic theory of gases to the motion of electrons, arrived at the same conclusion as Lorenz.
Up to 1900, however, the experimental values were too uncertain to allow any definite conclusion to be drawn. In that year Jaeger and Desselicht published the results of their investigation, which gave directly the ratio of the two conductivities for a number of metals and alloys. They found that for seven pure metals—lead, cadmium, tin, nickel, silver, zinc, and copper—the value of Lorenz's constant $K$ was nearly the same over the range $18^\circ$ to $100^\circ$ C. The mean value was $2.33 \times 10^{-8}$, $K$ being expressed in watts/can. sec. $^\circ$ C., $1A$ in ohms per $^\circ$ C., and $T$ being the absolute temperature. The few alloys that were tested gave higher values, and iron and aluminium were respectively higher and lower. Lees confirmed the value of Lorenz's constant down to $-170^\circ$ C., and showed a slight rise, and zinc, silver, copper showed a falling off in value in the order named. All the alloys tested gave increasingly high values with fall of temperature. Meinheit, who

medium conductors (Fig. 13), found that the conductivities of tin, lead, zinc, and aluminium steadily decreased towards the melting-point, where a sharp drop occurred. Taking Tansui's values for electrical conductivity he deduced that Lorenz's law held approximately up to the melting-points. The changes of electrical and thermal conductivity on melting were of the same order, but Lorenz's law did not hold for the liquid state. The conclusions of Angell as to aluminium are widely at variance with those of Komor. While both obtained about the same value for the conductivity at 100°C, the latter gives a value at 500°C of 0-36 and the former gives a value nearly three times as large. Angell's values of Lorenz's constant for nickel as well as aluminium show rapid increases with temperature.

At still higher temperatures Langmuir gives a value for Lorenz's constant for tungsten of 3-49 x 10^-4 at 1800°C, which means a comparatively small temperature coefficient on the value below 100°C. Worthing, however, does not agree with this value.

The law of Lorenz has therefore only been shown to hold for a certain number of pure metals over the range from about -100°C to 100°C or 200°C. Below this region it definitely fails; while above, further evidence will be necessary before it can be accepted. As regards alloys, those tested by Lees and by Jager and Diesselhorst have given higher values for Lorenz's constant than the pure metals and large temperature coefficients. Further, Gremichen 1 has shown that, in the case of copper and iron, small amounts of impurity lower the value nearly as much as a larger amount of a different metal.

(11.) Conductivity, Elasticity, and Density of Non-metals.—Thornton 2 has recently put forward a tentative suggestion as to a relationship of the above-mentioned constants. He shows that for such diverse substances as quartz, balt crown and soda glass, graphite, marble, mahogany, d.a., lignum, and paraffin wax, the thermal conductivity is proportional to \( \kappa_0 \), with being Young's modulus of elasticity and \( \rho \) the density. His figures for glass have, however, been criticised by Clarke. 3

(111.) Conductivity, Viscosity, and Specific Heat of Gases.—Many of the deductions as to the physical properties of gases, based on the kinetic theory, have been confirmed by experiment in a remarkable way. In the case of conductivity, Maxwell's prediction of a value for air of 0-000055 is well within the range of those found by experiment, the mean of which is given by Heran and Lamy 6 as 0-000052, while his value for hydrogen is being seven times that of air has been closely confirmed. Another deduction from the kinetic theory is that the conductivity of a gas is independent of its pressure, and, as mentioned above, this has been found to be true, except for very low pressures where the mean free path of the molecules becomes comparable with the thickness of the gas layer. For these very low pressures Naudy and Barry 6 and Kraften 7 have shown that the conductivity is nearly proportional to the pressure.

The important relation between the conductivity \( K \), specific heat at constant volume \( C_v \), and viscosity \( \eta \) of a gas is primarily due to Maxwell, who showed that, assuming molecules are point centres of repelling each other according to a fifth power law of distance, the value of \( f \) being 2-5.

A considerable amount of experimental evidence is available as bearing on this relation, and a summary of it, due to Heran and Lamy, is given in Table V. The value of \( C_v \) has been very seldom observed, but it can be deduced from determinations of \( C_p \) and of the ratio of \( C_v \) to \( C_p \). The viscosity can easily be measured. It will be noticed that for mountaineous gases the value of \( f \) agrees approximately with that given by Maxwell. For gases with higher degrees of freedom the value is less than 2-5, being in the case of the diatomic gases 1-75. So far, theory has been unable to account for this value, though various empirical laws have been promulgated by Jesus and others.

The determination of the conductivity of a mixture of gases from that of its constituents is sometimes a matter of practical importance. According to the kinetic theory it is given by

\[
K = \frac{K_1}{1 + A(p_1/p_0) + 1 + B(p_2/p_0)}
\]

\( K_1 \) and \( K_2 \) being the conductivities, and \( p_1 \) and \( p_2 \), the partial pressures of the two gases, and \( A \) and \( B \) being constants the values of which are

\[
A = \frac{1}{\sqrt{\left( 1 + \frac{\eta_2}{\eta_1} \right) \left( 1 + \frac{\eta_1}{\eta_2} \right) \left( 1 + \frac{\rho_2}{\rho_1} \right) \left( 1 + \frac{\rho_1}{\rho_2} \right)}}
\]

\[
B = \eta_2 A
\]

where \( \eta_1 \) and \( \eta_2 \) are the viscosities, and \( \rho \);

\[ ^4 \text{Proc. Roy. Soc., 1918, xxxv. 180.} \]
\[ ^5 \text{Proc. Roy. Soc., 1900, xxxvii, 254.} \]
\[ ^6 \text{Ann. der Phys., 1911, xxxiv, 503.} \]
\[ ^7 \text{Ibid.} \]
and \( m_2 \) the masses of the molecules of the two gases.

S. Weber \(^1\) has, however, shown that these theoretical values of \( A \) and \( B \) incorrectly give the conductivity of the mixture. The relationship can be expressed in the form above mentioned, but the values of \( A \) and \( B \) must be determined experimentally for each mixture. The table below, quoted from Weber, shows the difference between the experimental and theoretical values:

The variation in conductivity of a gas with temperature has also been considered in the light of the kinetic theory, according to which it should vary as the square root of the absolute temperature. This would give a temperature coefficient of 0.00183. The experimental values for air have varied from 0.0013 to 0.003. Recently, however, Keckner \(^2\) has shown that for five different gases the ratio of the conductivity to the viscosity is constant for temperatures from \(-80^\circ C\) to \(160^\circ C\). As regards viscosity, a formula due to Sutherland has been verified over a wide range of conditions, so that, if Keckner’s work is accepted, it can be applied to conductivity. This would give

\[ K_\theta = K_0 \left( \frac{\theta}{\theta + C} \right)^{\frac{1}{2}} \]

For air, taking \( C = 117 \), the temperature coefficient would be 0.0029.

II. APPLICATION OF THEORY TO PRACTICAL PROBLEMS

As has already been indicated, the problem arising out of the flow of heat can be considered under two heads, namely, those of the steady state and those of the variable state. In the former the temperature at each point throughout the body remains constant and the flow of heat depends on the conductivity; while in the latter, where the temperature is varying with time, the thermal capacity per unit volume, as well as the conductivity, becomes a determining factor.

\( \Theta (11) \) STEADY STATE - THE SHAPE FACTOR.

-If two isothermal surfaces are considered, differing in temperature by \( \theta \) and at an infinitely small distance \( dx \) apart, it has already been shown that the rate of heat loss is given by

\[ H = KA \frac{d\theta}{dx} \]

So that for isothermal surfaces which are at a finite distance apart we have

\[ H = \int fKd\theta \]

For most materials the conductivity \( K \) may be taken to be a linear function of the temperature, and hence the value of \( \int Kd\theta \) becomes the product of the conductivity for the mean temperature of the surfaces multiplied by the temperature difference between them.

The quantity \( 1 - \frac{1}{2}(dx/kA) \) depends entirely on the size and shape of the body and the position of the surfaces by which the heat enters and leaves the body, and has therefore been called by Langmuir, Adams, and McBride \(^3\) the "shape factor." \(^7\) The value of the factor for various shapes is given below, together with the solution of a few typical problems of heat flow.

\( \Theta (12) \) PLATE WALL OR SLAB.

The shape factor in this case is obviously the ratio of the area \( A \) to the thickness \( x \), and if the wall is homogeneous and of mean conductivity \( K \) the rate of heat flow through it is given by

\[ Q = \frac{xA}{KA(\theta_1 - \theta_2)/x} \]

If the wall is a composite one, being made up of a number of parallel layers of different materials of conductivities \( K_1, K_2, \ldots \) and thickness \( x_1, x_2, \ldots \), and if \( \theta_1, \theta_2, \ldots \) are the temperatures of the faces of the successive layers, then

\[ Q = \frac{x_1A}{x_1K_1(x_1/k_1 + x_2/k_2 + \ldots)} \]

where \( Q \) is the rate of heat flow through a unit area of the wall.

Eliminating the temperatures intermediate between \( \theta_1 \) and \( \theta_2 \) we obtain

\[ Q = \frac{x_1A}{x_1k_1 + x_2k_2 + \ldots} (\theta_1 - \theta_2) \]

\( \theta_1 - \theta_2 \) is the total difference of temperature through the wall, so that the composite wall of total thickness \( X \) is equivalent to a simple wall of this thickness and of conductivity \( K \), such that

\[ X = \frac{x_1}{K_1} + \frac{x_2}{K_2} + \ldots \]

The formula enables one to calculate the heat flow through a composite wall if the constant factors.

\[^2\] Phys. Zeit., 1911, XI. 1061; 1913, XIV. 324.

HEAT, CONDUCTION OF

ductivities and thicknesses of the components are known and the total temperature drop through the wall.

In many practical problems the surface-temperatures of the wall or slab are not known and cannot conveniently be measured, e.g. a boiler plate heated on one side by hot gases and cooled on the other by water; or of the wall of a dwelling-house or a cold store, the two faces of which are exposed to air at different temperatures. It is desired to calculate the heat transfer from the known temperature of the gas or liquid in contact with each face of the wall. The general treatment of this problem is beyond the scope of the present article, but it may be useful to give an approximate solution of the cases of a wall the faces of which are exposed to still air at temperatures not differing greatly.

If \( \theta_1 \) and \( \theta_2 \) are the temperatures of air, and \( \theta_1 \) and \( \theta_2 \) the temperatures of the faces of the wall, then, since the heat transferred between a surface of the wall and the surrounding air is nearly proportional to differences in temperature,

\[
Q = E(\theta_1 - \theta_2) = E(\theta_1 - \theta_2) = \frac{K(\theta_1 - \theta_2)}{x},
\]

where \( Q \) is the rate of heat transfer per unit area.

Eliminating \( \theta_1 \) and \( \theta_2 \) we obtain

\[
Q = \frac{h_1 - h_2}{2} + \frac{\theta_1 - \theta_2}{\Delta T}.
\]

For air temperatures about that of the atmosphere, and for surfaces which are plane and vertical and are full radiators, the value of \( E \) is roughly 0.0002 calories per sq. cm, per second per \( 1^\circ \) C difference of temperature. The contributions of radiation and convection towards this value are of the same order of magnitude.

Some applications of the formula can now be considered.

(a) If the wall is of thin metal (say, copper), \( x \) will be a fraction of a centimetre and \( K \) will be nearly 10 C.G.S. units. The value of \( x/K \) will be negligible as compared with \( 2/\ell \), and the heat transfer will be governed entirely by emission coefficients of the wall. If the metal surface is polished, its power of absorbing or emitting radiation will be very small, and the value of the emission coefficient \( E \) will be much less than that given above.

(b) If the wall is of thin paper of conductivity 0·0003 C.G.S. units, \( x/K \) would still be small as compared with \( 2/\ell \); while, since paper is a good radiator, \( E \) will be much greater than for the polished metal, so that

\[
\text{we have the apparent anomaly of a thin-paper wall transmitting more heat than a metal wall of the same thickness.}
\]

(c) If the wall is thick (say 100 cm), and of good insulating material like granulated cork \( (K=0·0001) \), \( x/K \) would be large compared with \( 2/\ell \), and the transmission of heat would be governed almost entirely by the conductivity of the material of the wall and not by its emission coefficient.

(ii) Cylindrical or Cylindrical Shell. — The shape factor in this case is

\[
Q = \frac{2\pi l}{\sqrt{\ln (a/b)(b/a)}} = \frac{2\pi l}{\ln (a/b)},
\]

where \( a \) and \( b \) are the internal and external diameters and \( l \) is the length, which is supposed to be great compared with the diameter. If the temperatures of the internal and external surfaces are known, the above formula enables the heat transmission to be calculated.

As in the case of a wall, however, it may not be convenient to determine surface temperatures. Taking as an example a steam-pipe covered with insulating material, the inner temperature of the lagging may be assumed to be that of the steam, since there will be no appreciable gradient through the pipe. It is desired to calculate the heat loss, knowing the temperature of the surrounding air. Proceeding in a similar way to that followed in the case of a wall we get

\[
Q = \frac{2\pi l}{\ln (a/b)}(\theta_1 - \theta_2),
\]

where \( \theta_1 \) and \( \theta_2 \) are the inner and outer temperatures of the lagging and \( \theta_2 \) that of the air. The elimination of \( \theta_2 \) gives

\[
Q = \frac{2\pi l}{\ln (a/b)}(\theta_1 - \theta_2).
\]

The heat loss from the bare pipe would be

\[
Q = 2\pi l(\theta_1 - \theta_2).
\]

It does not follow that the heat loss from the bare pipe would always be greater than that from the covered pipe. If the covering were of metal, it is obvious that the reverse would be the case, and even with medium conductors it is possible that the covered pipe would give the greater loss. Pécelé,2 who was probably the first to draw attention to this point, took the case of a pipe 12 cm. in diameter and with insulation varying in thickness from 1 cm. to 12 cm. If the conductivity of the insulation was 0·00012 C.G.S. units, the heat transmission diminished with increasing thickness; if the conductivity was 0·002, or sixteen times as great, the transmission was approximately constant for all thicknesses; and if the conductivity was 0·004 the heat loss increased with the thick-

---

2 Traité de la chaleur, 1849.
A full treatment of the subject has more recently been given by Porter.\(^1\)

(iii.) Sphere or Spherical Shell.—The shape factor is \(2\pi a b (b-a)\), where \(a\) and \(b\) are the internal and external diameters. The case of logging surrounding a sphere can be treated in the same way as that for a cylinder, but it is not of much practical importance.

(iv.) Rectangular Prism or Box.—Examples of this case are commonly met with in practice, e.g. a furnace chamber of cubical or rectangular shape surrounded by walls of uniform thickness. No rigid mathematical solution has yet been obtained for the shape factor, but assuming that the inner and outer surfaces are isothermal, Langmuir, Adams, and Melville\(^2\) have given an approximate formula. They take first the case of a long hollow prism of rectangular section and uniform thickness. If \(A\) is the area of the interior surface and \(t\) the thickness of the wall, and if the lines of heat flow were normal to the interior surface, the shape factor would be \(A/t\). The lines of heat flow will, however, be normal only for the central portion of each face. Toward the edges they tend to become radial, though they are not rectilinear. This is illustrated in Fig. 21, which shows the lines of heat flow and the isothermals for a portion of the section of the prism. The edges will tend to increase the shape factor, and the amount by which the factor is made to exceed \(A/t\) may be regarded as the shape factor of the edge itself. By a series of approximations the shape factor of the edge is shown to be 0.777, where \(t\) is its length.

Next, the case of a cubical or rectangular box of uniform thickness is taken. In addition to the edges, which have the same factor as in the case of the prism, there is the effect of the corners. The shape factor of each corner is estimated to be 0.1611, where \(t\) is the thickness of the wall of the box. The edges and corners are far dealt with are termed “square” edges and corners (see Fig. 25).

If two opposite walls of the box are supposed to approach each other until they nearly touch (see Fig. 20), the square edges \(A\) and \(B\) form practically one edge, which is called a “plane” edge and has a shape factor nearly double that of two “square” edges. Similarly the four “square” corners \(A\), \(B\), \(C\), \(D\) now form the two “plane” corners \(AB\) and \(CD\), for which shape factors are calculated. An example of the case illustrated in Fig. 20 is a rectangular plate surrounded by a uniform thickness of material.

It is interesting to note that Langmuir, Adams, and Melville confirmed their theoretical deductions by experiments based on the analogy of heat flow through walls and the flow of electricity through an electrolyte of the same shape. Elementary cells, prisms, cylinders, etc., of the electrolyte (sulphuric acid) were formed by joining together suitable plates of glass and copper, and the electrical conductivities of the various shapes of electrolyte were compared. In this way the shape factors of a square edge and plane edge were found to be 0.84 and 0.83 while the theory has given 0.477 and 0.824. The values of a square corner and plane corner were 0.151 and 0.0871. The experimental

---

Example of Calculation of Slope Factor.—Take an electrically heated wire with a thickness of half an inch, and of inside dimension 8 x 10 x 20 in., which are all greater than \( \frac{T}{2} \). Then

\[
A = 2 \times 8 \times 10 \times 20 = 3200 \text{ square inches}
\]

\[
+ 2 \times 8 \times 20 = 640 \text{ square inches}
\]

\[
+ 2 \times 10 \times 20 = 400 \text{ square inches}
\]

\[
S = 880 \text{ square inches}
\]

\[
2A = (8 + 10 + 20) = 532 \text{ inches}.
\]

Hence \( S \) is the sum of \( \frac{880}{S} = 116 \) inches.

\[
+ 0.64 \times 20 = 256 \text{ inches}
\]

\[
+ 1.28 \times 8 = 10.24 \text{ inches}
\]

\[
= 301.28 \text{ inches}
\]

It is interesting to compare this result with two other methods which are sometimes adopted. Calculating the slope factors from the areas of the inner and outer surfaces by means of the formula \( S = A / \theta \), and taking either the arithmetic or geometric means between the two values, the following results are obtained for the oven:

| Arithmetic mean | 363.3 |
| Geometric mean | 244.4 |

These results differ considerably from the other values.

The formulae which have been summarised above are a useful contribution towards the solution of the problem of calculating the heat losses from rectangular-shaped bodies covered with a uniform thickness of insulation. It must not be forgotten, however, that they apply only where the inner and outer surfaces are isothermal, and that this condition is often not realised in practice.

§ (12) VARIABLE STATE.—Heat Diffusivity.

All problems connected with the variable flow of heat depend on particular solutions of Fourier’s fundamental equation,

\[
\frac{\partial \theta}{\partial \tau} = K \left( \frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2} \right),
\]

in which \( K, \sigma, \rho \) are the conductivity, specific heat and mass density of the body, \( \tau \) the time, and \( \theta \) the temperature at any point whose coordinates are \( x, y, z \). This equation expresses the fact that, in the case of a constant density, the rate of flow in a direction is equal to the rate of change of temperature with distance in the direction. Heat will flow into the material during one half period of the temperature oscillation and out of the material during the other half period. It can be shown that the heat flow during a half period is

\[
H = \theta_0 K \sqrt{2 \pi}.
\]

(a) Application: Diurnal and Annual Waves in the Earth’s Crust.—The surface of the earth is subjected to daily and annual waves of temperature which, to a first approximation, can be assumed to be simple harmonic oscillations. The square root of the ratio of the surface, and so on. For these cases Fourier’s equation reduces to

\[
\frac{\partial \theta}{\partial \tau} = h \frac{\partial \theta}{\partial x^2}
\]

They can conveniently be considered under various heads according to the dimensions of the body, its initial temperature distribution, and the mode of heat supply.

(i) Periodic Flow from a Plane Surface into a Semi-infinite Solid.—Suppose that the heat supply is such as to produce simple harmonic variations of temperature at the surface of an infinite solid, and that \( \theta_0 \) is the amplitude and \( T \) the period of the oscillation. Then the temperature of the surface at any time is given by

\[
\theta = \theta_0 \sin \frac{2 \pi t}{T}.
\]

It can be shown that the general solution of Fourier’s equation, which satisfies this boundary condition, is

\[
\theta = \theta_0 \left( \frac{2 \pi}{T} \right)^{\frac{1}{2}} \sin \left( \frac{2 \pi}{T} \right) \left( T - h \sqrt{\frac{2 \pi}{T}} \right),
\]

where \( \theta \) is the temperature at a distance \( x \) from the surface. It will be seen from this form of this equation that the temperature at any point will vary periodically and that the amplitude of the oscillation will diminish with the distance from the surface. The following characteristics of the wave propagation can be deduced from the equation:

Amplitude at any point = \( \theta_0 \left( \frac{2 \pi}{T} \right)^{\frac{1}{2}} \)

Velocity of propagation = \( 2h \sqrt{\frac{\pi}{T}} \)

Wave-length = \( 2h \sqrt{\frac{\pi}{T}} \).

The "lag," which can be defined as the time taken for any crest, trough, or other phase of the wave to reach a point at a distance \( x \) from the surface, is equal to \( (x/2h) \sqrt{8 \pi/T} \).

Heat will flow into the material during one half period of the temperature oscillation and out of the material during the other half period. It can be shown that the heat flow during a half period is

\[
H = \theta_0 K \sqrt{2 \pi}.
\]

1 See, e.g., Ingenohl and Rebol, "Introduction to the Mathematical Theory of Heat Conduction" (John & Co.), 1913.

2 See also "Heat Conduction of Mathematical Theory," equation (19).
the periods of the annual and daily waves is about 20(\sqrt{20} \approx 10)\). So that we can at once deduce from the expressions given above that the wave length and the lag at any point for the annual wave will be twenty times those for a daily wave. The amplitude of the latter will fall off very rapidly with depth. Taking the case of a daily wave with a range of $15^\circ$ C.,

\begin{align*}
\text{period} &= 10\text{ cm.,} \\
\text{amplitude} &= 10^2 \text{ C.}
\end{align*}

Since the mean temperature of the soil is $5^\circ$ C., an amplitude of $10^2$ C. will just be sufficient to take the soil $0^\circ$ C., so that the freezing temperature will only penetrate to a depth of 8 cm. The lag at this depth will be about 23 hours. If an annual wave had the same range as the daily wave taken above, the freezing temperature would penetrate twenty times as far and the lag at this point would be 40 days.

The mathematical formula given above apply only to simple harmonic oscillations of temperature. The annual wave, in particular, departs considerably from the simple form, and it may therefore be necessary to analyze it, according to the Fourier method, into a number of simple harmonic components. Those of short period, like the daily wave, rapidly become insensible as the depth is increased.

A number of observers have studied the temperature waves in soil for the purpose of measuring its diffusivity, and some of their values are given in the table below:

<table>
<thead>
<tr>
<th>Soil</th>

</tbody>
</table>

The two last-mentioned observers used platinum thermometers, which are much to be preferred to the mercury thermometers with long stems used in some of the earlier work. Collioure points out that water has a very large effect on the diffusivity of the soil. Its presence increases both the conductivity and the heat capacity, but the former in a greater extent, so that the diffusivity is increased. Under very extreme conditions the diffusivity may vary from 0.001 to 0.030.

(ii) Function of Slab at Temperature $\theta_0$ between two Infinite Blocks of same Material at $0^\circ$ C.—If the slab is of thickness $2l$ it can be shown 3 that the temperature at a point at a distance $x$ from the central plane of the slab is given by

\begin{equation}
\theta = \frac{\theta_0}{\sqrt{2\pi l}} e^{-\frac{x^2}{2l^2}}.
\end{equation}

Values of this integral (the "probability integral"), which is frequently met with in the solution of problems of variable heat flow, will be found in Tables of Mathematical Functions. 4

As an example we may take the case of concrete, originally at a temperature of $10^\circ$ C., which is poured into a trench 60 cm. wide cut in the soil. If the temperature of the soil is $-5^\circ$ C., it is desired to know whether the concrete will have time to set before it is frozen.

For this purpose we can calculate how long the freezing temperature will take to penetrate to a depth of (say) 6 cm. below the surface of the concrete, which it is assumed has the same diffusivity as the soil (0.005). Here $l=30$ cm., $x=25$ cm., while $\theta_0=15^\circ$ and freezing temperature $=-5^\circ$, both relative to the soil, so that

\begin{align*}
\theta &= \theta_0 \\
&= 15 \frac{2\pi}{\sqrt{2\pi l}} e^{-\frac{x^2}{2l^2}}.
\end{align*}

The limits of the integral may be called $q$ and $-\theta_0$, and by a process of trial from the table of values it can be shown that $q=0.005$ nearly, so that $l$ is over 4 days.

It is interesting to note that as the conditions of symmetry require that there can be no transfer of heat across the middle plane of the slab, the above solution applies also to the case of a slab of half the thickness one face of which is placed in contact with an infinite block and the other protected from heat loss.

(iii) Semi-infinite Solid at $0^\circ$ with Boundary Surface maintained at $\theta_0$.—This case differs from the first case discussed above in that the boundary temperature instead of varying periodically is supposed to be suddenly altered to $\theta_0$ and then maintained constant.

It can be shown 3 that the temperature $\theta$ at a distance $x$ below the surface is given by

\begin{equation}
\theta = \frac{\theta_0}{\sqrt{2\pi l}} e^{-\frac{x^2}{2l^2}}.
\end{equation}

From this equation it is easy to deduce the

---

1. Ingensall and Zobel, loc. cit. p. 76.
2. Weisbach, Theorie und Praxis der Ausleger- 
   rechnung, p. 257, or Ingensall and Zobel, loc. cit. p. 166.
3. Ingensall and Zobel, loc. cit. p. 78.

4. Ingensall and Zobel, loc. cit. p. 78.
"law of times" according to which the times required for any two points to reach the same temperature are proportional to the squares of their distances from the boundary plane.

As an application of the above equation we may take the case of a mass of concrete (differentivity 0.005) at a temperature of 20° the surface of which is suddenly raised 70°C. It is required to ascertain how long a temperature of 100°C will take to penetrate a distance of 30 cm. Here \( \theta_0 = 720° \) and \( \theta = 80° \), measured relative to the original temperature, and \( t \) is found to be about 36,500 seconds or 10 hours.

(a) Application: Cooling of the Earth.—The equation above can also be used for the solution of the problem of the time taken for the cooling of the earth to its present condition, neglecting the effect of the earth’s curvature. By differentiating the equation it can be shown that

\[
t = \frac{\theta_0^2}{\pi^2 (d\theta/dx)^2}
\]

Kelvin assumed the original temperature \( \theta_0 \) to be 3900°C, \( \pi^2 = 0.1178 \), and the surface gradient \( (d\theta/dx) \) to be 1°C in 2770 cm., and obtained a value of 100 million years. Even allowing wide limits of error, this estimate is far below that based on geological considerations. It has been suggested that a probable explanation of the discrepancy between the two estimates is supplied by the recent discovery of the continuous generation of heat by the disintegration of radioactive compounds.

(ii.) Slab at Uniform Temperature: one Face raised to Temperature \( \theta_0 \) and kept constant, the other protected from Heat Loss.—If 1/2 is the thickness of the slab the relation between time and the temperature of the protected face is shown by Ingersoll and Zobel \(^2\) to be

\[
\theta = \theta_0 \left( 1 - \frac{4}{\pi^2} \frac{e^{-2\theta/\theta_0}}{1} + \frac{4}{\pi^2} \frac{\theta_t/\theta_0^2}{1} \right)
\]

Generally it is only necessary to take account of the first two or three terms of this expression. As in the other case of a slab dealt with above, the equation also gives the temperature rise of central plane of a slab of twice the thickness

\[ \text{(i.e. \( t \) each face of which is suddenly raised to and maintained at \( \theta_0 \).} \]

As an example of the above conditions we may take a wall of concrete backed by a wooden casing or a floor of masonry or concrete on which is piled some poorly conducting but inflammable material. It is desired to know how soon a fire on one side of the wall would cause a dangerously high temperature to penetrate to the other side. It follows at once that the effectiveness of the wall or floor in preventing fire depends on a low value of the differentivity rather than the conductivity, and that the time taken for a dangerous temperature to penetrate to the rear face will vary as the square of the thickness (cf. law of times above).

The solution given requires that the face of the wall should be suddenly raised to a temperature and maintained there. In practice this condition would not be realised, but Ingersoll and Zobel show that a solution may be arrived at by the device of imagining a layer to be added to the outside of the wall, the surface of which is suddenly raised to a temperature \( \theta_0' \). By suitably choosing the added thickness and the temperature \( \theta_0' \), a very close approximation to the temperature rise of the actual surface of the wall can be obtained.

For most purposes, however, a sufficiently close solution is given by using the mean value of \( \theta_0' \).

For further examples of practical problems depending on the variable state, reference may be made to a standard textbook, such as that of Ingersoll and Zobel, from which many of the solutions given above have been drawn.

HEAT, CONDUCTION OF: MATHEMATICAL THEORY

Conduction is the name given to the process by which heat is transferred from one portion of a body to another portion immediately adjacent to it, across the common boundary or interface, in consequence of inequality of temperature. It is to be distinguished from Radiation, which may take place between bodies which are at a distance apart, without material connection, and from Convection, in which the transfer is produced by currents in the substance.

The points of a body which at a given instant have an assigned temperature \( \phi \) lie on a surface, called an "isothermal" surface. If we imagine a series of such surfaces to be drawn for equal small intervals of \( \phi \) we obtain a complete mental picture of the instantaneous distribution of temperature. In general the configuration of these surfaces changes from instant to instant. When on the other hand it is permanent we have what is called a "stationary" state.

The mathematical theory of conduction starts with the assumption that in an isotropic substance the flux of heat across a surface element drawn (in any direction) through an internal point \( P \) is in the direction of diminishing temperature, and is proportional to the space-rate at which the temperature falls in the direction of the normal. Hence if \( DS \) be the area of the element, and \( k \) an element of the normal to it, the positive or negative amount of heat which crosses in time \( \Delta t \), in the direction of \( \phi n \), is

\[
-k \frac{\partial \phi}{\partial n} DS, \Delta t \quad \quad \quad (1)
\]

where \( k \) is a coefficient called the "thermal conductivity." The value of \( k \) depends of course on the thermometric scale adopted, and on the nature of the substance. It varies also to a slight extent with \( \phi \), but this is not important unless the range of temperatures be considerable, and is usually ignored in the mathematical theory. It is evident that the flux is greatest in the direction of the normal to the isothermal surface through \( P \), and zero in tangential directions.

The simplest problems are those of linear flow, where the isothermal surfaces are parallel planes, as when the faces of a large flat plate or slab are subjected to given changes of temperature, uniform over each. Taking the axis of \( x \) normal to these planes we calculate the amount of heat gained in time \( \Delta t \) by unit area of a stratum of thickness \( \Delta x \). The amount which enters the outer face is

\[
-k \frac{\partial \phi}{\partial x} \Delta x, \Delta t
\]

whilst an amount

\[
-k \left( \frac{\partial \phi}{\partial x} + \frac{\partial \phi}{\partial x} \right) \Delta x, \Delta t
\]

leaves by the front face. There is thus on the whole a (positive or negative) gain of amount

\[
k \frac{\partial \phi}{\partial x} \Delta x, \Delta t
\]

To find the consequent change of temperature we divide by the thermal capacity of the portion of the stratum considered, viz. \( \rho c \Delta x \), where \( \rho \) is the density, and \( c \) the specific heat per unit mass. Hence

\[
\frac{\partial \rho c \phi}{\partial \rho c \partial x} = k \frac{\partial \phi}{\partial x} \Delta x, \Delta t
\]

or

\[
\frac{\partial \phi}{\partial \rho c \partial x} = k \frac{\partial \phi}{\partial x} \Delta x, \Delta t
\]

whence

\[
k = \frac{\partial \phi}{\partial \rho c \partial x}
\]

This is the quantity \( k \), rather than \( k \), which determines the rapidity with which temperature changes ensue, under assigned conditions, in a body of given dimensions; \( k \) is therefore called the "thermometric" conductivity. It appears from (2) that the dimensions of \( k \) are those of the square of a length divided by a time. Hence in geometrically similar bodies of the same material the times in which analogous changes of temperature take place are proportional to the squares of the linear dimensions.

In a stationary state we have \( \phi = \phi \Delta t = 0 \) and, therefore, from (2), \( \phi = k \Delta t \), the graph of which is a straight line. Thus if the two faces \( x = 0, x = l \) (say) of a slab be maintained at given temperatures \( \phi_0, \phi_\rho \), we have

\[
\phi = \phi_0 + (\phi_\rho - \phi_0) \frac{x}{l}
\]

The simplest example of a variable temperature is that of a solid bounded by the plane \( x = 0 \) and extending to infinity in the direction of \( x \) positive, when the surface is subject to a periodic variation

\[
\phi = \phi_0 \cos \omega t
\]

The work is shortened if we replace (5) by \( \phi = \phi_0 \cos \omega t \) and afterwards reject the imaginary part of the result. Assuming \( \phi = u e^{i \omega t} \), where \( u \) involves only, we find on substitution in (2)

\[
d^2u \Delta x = -k u, \Delta x
\]

whence

\[
u = A e^{(1+i \omega) x} + B e^{-(1+i \omega) x}
\]

provided

\[
u = \frac{A}{2x}
\]

Since in our case \( u \) must not become infinite with \( x \), \( A \) must vanish, and putting \( x = 0 \) we
HEAT, CONDUCTION OF: MATHEMATICAL THEORY

The fluctuations of temperature are propagated inwards without change of the period \((2\pi/\alpha)\), with the wave-velocity \(c/\mu\) or \(\sqrt{(2\alpha)}\), but diminish in amplitude as they proceed, according to the law \(e^{-mx}\). In the space of a wave-length \((2\pi/m)\) the ratio in which the amplitude is diminished is \(e^{-2\pi}\) or \(1/1256\). This example is of interest as illustrating the way in which the daily and seasonal variations of temperature at the earth's surface are modified as they penetrate into the ground. It appears from (8) that the more rapid fluctuations have less penetration than the slower. Thus at a certain depth the alternations of summer and winter may be still sensible, whilst the daily variations are imperceptible. The progressive change of phase is also to be noticed. At a depth \(\pi/m\) the phase is inverted, the temperature being (for instance) highest in winter and lowest in summer.

If we start with an initial distribution
\[ \theta = A \sin mx \]  
(10)
in a solid unlimited both ways, we have, assuming \(\theta = \mu \sin mx\), where \(\pi\) involves \(t\) only,
\[ \frac{d\mu }{dt} + \sin^2 \mu = 0. \]  
(11)
Hence, determining the constant \(a\) so as to agree with (10) when \(t=0\),
\[ \theta = A e^{-x \sin \mu} \sin mx. \]  
(12)
This is a simple example of a "normal mode" of decay of inequalities of temperature in a body left to itself. The smaller the scale \((2\pi/m)\) of the inequalities the more rapidly is the process of smoothing out. The result may be adapted to the case of a slab bounded by the planes \(x=0, x=L\), by making \(x = mx\), where \(\pi\) is any integer. The normal modes corresponding to \(x = 1, 2, 3, \ldots\) respectively, may be superposed; thus
\[ \theta = B \sin \frac{\pi x}{L} + B \sin \frac{2\pi x}{L} \ldots \]  
(13)
where
\[ \lambda_n = \frac{\pi}{L}. \]  
(14)
The coefficients \(B_n\) may be determined so that (13) shall represent, for \(t=0\), any arbitrary initial distribution of temperature in the slab (see "Fourier's Theorem"). As \(t\) increases, the successive terms in (13) gradually diminish, each more rapidly than the preceding one, so that the first component is the last to survive in appreciable amplitude.

To investigate the propagation of heat in a slab, the boundary conditions may be taken account of. The rate of loss per unit area of the surface is \(E\), where \(\theta\) is the excess of temperature above that of the environment, and \(E\) is a constant, called the "emissivity," whose value depends on the nature of the surface. The loss in time \(dt\) to an element \(dx\) of the bar, from this cause, is \(E\theta\), where \(p\) is the parameter of the cross-sectional area. This leads to the equation
\[ \frac{d^2 \theta}{dx^2} = \frac{1}{k} \frac{\partial \theta}{\partial t}, \]  
(16)
where
\[ k = \frac{E}{p^2}. \]  
(16)

\(S\) denoting the sectional area.

In a stationary state we have
\[ \frac{d\theta}{dx} = \frac{h}{k}, \]  
(17)
whence
\[ \theta = Ae^{mx} + Be^{-mx}. \]  
(18)
if
\[ m^2 = \frac{h}{k}. \]  
(19)
Thus if the ends \((x=0, x=L)\) be maintained at the constant temperatures \(\theta_1, \theta_2\) respectively, we find
\[ \theta = \theta_1 \sinh m(L-x) + \theta_2 \sinh mx \]  
(20)
\[ \frac{\sinh mL}{\sinh mL} \]
if the bar is infinitely long we have the simpler formula
\[ \theta = \theta_1 e^{mx}. \]  
(21)
To investigate the case of a very long bar whose extremity \((x=0)\) is subject to a given periodic variation, we assume in the first instance
\[ \theta = \theta_0 e^{it} \]  
(22)
as the prescribed terminal temperature. The equation (15) then gives
\[ \frac{d^2 \theta}{dx^2} + \frac{h \theta}{k} = 0. \]  
(23)
To solve this we introduce auxiliary constants \(r\) and \(\alpha\), such that
\[ \frac{h + i\alpha}{k} = \frac{r^2 - \left(\frac{\alpha + i\beta}{k}\right)}{k}, \]  
(24)
that is
\[ r^2 = \frac{\sqrt{(\alpha^2 + \beta^2)}}{k}, \tan 2c = \frac{\alpha}{h}. \]  
(25)
Then, writing for shortness
\[ \alpha = r \cos \epsilon, \beta = r \sin \epsilon, \]  
(26)
we have
\[ \frac{\partial \theta}{\partial x} = (a + i\beta) \theta, \]  
(27)
whence
\[ \theta = \left[(Ae^{a + i\beta})^x + Be^{-(a + i\beta)x}\right] e^{it}. \]  
(28)
Since \(\theta\) is to remain finite for \(x=\infty\), we have \(A=0\) and, putting \(x=0\), we find \(B = \theta_0\), by (22). Hence taking the real part
\[ \theta = \theta_0 e^{\alpha x} \cos (\beta x). \]  
(29)
corresponding to the prescribed oscillation \(\theta_0 e^{it}\) at \(x=0\). This contains the theory of an important experimental method.
HEAT, CONDUCTION OF: MATHEMATICAL THEORY

The simplest case of three-dimensional flow of heat is that of symmetry about a point. If \( \theta \) be a function of \( r \), the distance from the origin, and \( t \), only, the flux outwards across a spherical surface of radius \( r \) in time \( t \) is

\[
-\frac{k}{\alpha} \frac{\partial T}{\partial r}
\]

A spherical stratum whose inner and outer radii are \( r \) and \( r + dr \) therefore gains heat to the amount

\[
4\pi k \frac{\partial T}{\partial r} (r^{2} \frac{\partial T}{\partial r}) dr
\]

Since the thermal capacity of the stratum is \( 4\pi \kappa \rho \), the gain is also expressed by

\[
4\pi \kappa \rho \frac{\partial T}{\partial t} = 4\pi k \left( r^{2} \frac{\partial T}{\partial r} \right) dr
\]

Hence

\[
\frac{\partial T}{\partial r} = \frac{k}{\kappa \rho} \left( r^{2} \frac{\partial T}{\partial r} \right)
\]  

where \( k = \kappa \rho \) as before. The equation may also be written

\[
\frac{\partial T}{\partial r} = \frac{k}{\kappa \rho} (r^{2} \frac{\partial T}{\partial r})
\]  

In a stationary state \( \frac{\partial T}{\partial \tau} = 0 \), and therefore

\[
\theta = A + \frac{B}{r}
\]  

In the case of a spherical shell of inner and outer radii \( a \) and \( b \), respectively, and temperatures \( \theta_{1} \) and \( \theta_{2} \), we have

\[
\theta_{1} = A + \frac{B}{a}, \quad \theta_{2} = A + \frac{B}{b}
\]

Then

\[
B = (\theta_{1} - \theta_{2}) \left( \frac{ab}{b - a} \right)
\]

Hence

\[
\theta = A + \frac{B}{r} \left( \frac{ab}{b - a} \right) (\theta_{1} - \theta_{2})
\]

And if \( Q \) denote the outward flux per second,

\[
Q = \frac{\partial T}{\partial r} = \frac{k}{\kappa \rho} (r^{2} \frac{\partial T}{\partial r})
\]

In a sphere which is complete to the centre we must have \( B = 0 \); the only stationary condition is then one of uniform temperature. The second term in (32) would correspond to the case of a steady source of heat at the centre.

When a solid sphere has an arbitrary initial (symmetrical) distribution of temperature, whilst its surface is maintained at a constant temperature (which we may take as zero), the procedure is to ascertain the various "normal modes." Assuming that \( \theta \) varies as \( e^{\lambda t} \), we have from (31)

\[
\frac{\partial^{2} \theta}{\partial r^{2}} + \lambda \theta = 0
\]

Hence, putting \( \lambda / \kappa = \omega^{2} \),

\[ \theta = A \cos \omega t + B \sin \omega t \]

Since \( \omega \) must be finite at the centre, \( A = 0 \); and since it is to vanish at the surface \( r = a \) we must have \( \sin \omega a = 0 \), or \( \omega a = \pi, 2\pi, \ldots \) where \( \pi \) is integral. The normal modes are therefore of the type

\[
\theta = \frac{B}{r} e^{-\lambda r} \sin \frac{\pi \omega}{a}
\]

where

\[
\lambda = \frac{\pi^{2} \omega^{2}}{a^{2}}
\]

By superposition of the modes \( z = 1, 2, 3, \ldots \), it is possible to represent the result of any symmetrical initial distribution. The most persistent mode is that for which \( z = 1 \).

When the surface is not maintained at constant temperature but radiates into surroundings of temperature zero, the total flux outwards will be \( \Theta \). \( 4\pi a^{2} \). The condition to be satisfied for \( r = a \) is therefore

\[
-\frac{k}{\kappa \rho} \frac{\partial T}{\partial r} = \Theta
\]

Hence, referring to (34), with \( A = 0 \), and putting

\[
\frac{\Theta}{B} = \frac{\pi \omega}{a}
\]

we find

\[
\tan \omega a = \frac{\omega a}{1 - \omega a}
\]

This equation determines the admissible values of \( \omega a \). The roots are determined graphically by the intersections of the curves

\[
y = \tan \omega a, \quad y = \frac{x}{1 - \omega a}
\]

It appears on drawing the het that if \( \omega a < 1 \), the lowest positive root lies between 0 and \( \omega a \), whilst if \( \omega a > 1 \) it lies between \( \omega a \) and \( \pi \). The corresponding most persistent normal mode is

\[
\theta = \frac{B}{r} e^{-\omega a r} \sin \omega a r
\]

In the case of symmetry about an axis, the consideration of the flow of heat is in and out of a cylindrical shell of radius \( r \) and thickness \( dr \) leads to the equation

\[
\frac{\partial T}{\partial r} = \frac{1}{\kappa} \left( \frac{\partial T}{\partial r} \right)
\]

The condition for stationary temperature is that \( \frac{\partial T}{\partial t} \) should vanish, and hence we must have

\[
\frac{\partial T}{\partial r} = \Theta \log r
\]

For a solid cylinder we must have \( B = 0 \) unless there is a source of heat at the axis. In the case of a pipe whose inner and outer radii are \( r_{1} \), \( r_{2} \) we find

\[
\theta = A \log (r_{2}/r_{1}) + B \log (r_{1}/r_{2}) + C
\]

The general equation of conduction in three dimensions is obtained by calculating the flow of heat in and out of a rectangular element of volume \( dx dy dz \). As in the case of linear
HEAT, CONVECTION OF

flow the gain of heat in time \( \tau \) due to the two
to the is found to be

\[ \frac{\partial u}{\partial \tau} = 0. \]

Adding the gains due to the remaining pairs
of faces we have

\[ \frac{\partial u}{\partial \tau} = \left( \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} + \frac{\partial u}{\partial z} \right). \] (43)

From this the particular cases (30) and (42)
might be derived by transformation of co-
ordinates. The expression in brackets is often
denoted by \( V^3 \). It gives a sort of
measure of the extent to which the average
temperature in the immediate neighbourhood
of \((x, y, z)\) exceeds the temperature at
this point itself. Thus the excess of temperature
at an adjacent point \((x+\xi, y+\eta, z+\zeta)\) is, to
the second order,

\[ \frac{\partial u}{\partial \tau} = \frac{\partial u}{\partial x} \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} \frac{\partial u}{\partial y} + \frac{\partial u}{\partial z} \frac{\partial u}{\partial z} + \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \]

\[ + \frac{\partial^2 u}{\partial x \partial y} + \frac{\partial^2 u}{\partial x \partial z} + \frac{\partial^2 u}{\partial y \partial z}. \] (46)

The average values of \( x, y, z \) over a spherical
region of small radius \( r \) having its centre at
\((x, y, z)\) are each equal to \( \frac{r^3}{3} \), whilst the
averages of the remaining functions in (40)
are zero, since they are as much negative as
positive. The average excess is accordingly

\[ V^3 \cdot 4r^3. \] (47)

Reversing the sign, the expression \( \frac{\partial u}{\partial \tau} \)
is called the "concentration" of \( \theta \) at the point
\((x, y, z)\).

The condition of stationary temperature is

\[ \frac{\partial u}{\partial \tau} = 0. \] (48)

This is identical in form with the equation
satisfied by the gravitational or the electric
potential in free space. Consequently many
of the theorems of Attraction and Electro-
statics have their analogues in the present
subject. For instance, when the surface of a
solid of any form is maintained at a uniform
temperature the temperature (when stationary)
must be uniform throughout the interior.

So far, isotropic substances have been in
view. In a crystalline structure the flux of
heat across any surface is not determined
solely by the temperature gradient in the
direction of the normal. The natural exten-
sion of the previous assumption is that the
fluxes per unit area and per unit time across
surfaces perpendicular to \( x, y, z \) respectively are

\[ u = - \left( k_{11} \frac{\partial u}{\partial x} + k_{12} \frac{\partial u}{\partial y} + k_{13} \frac{\partial u}{\partial z} \right) \]

\[ v = - \left( k_{21} \frac{\partial u}{\partial x} + k_{22} \frac{\partial u}{\partial y} + k_{23} \frac{\partial u}{\partial z} \right), \] (49)

\[ w = - \left( k_{31} \frac{\partial u}{\partial x} + k_{32} \frac{\partial u}{\partial y} + k_{33} \frac{\partial u}{\partial z} \right). \]

The usual method leads to

\[ \rho c \frac{\partial u}{\partial \tau} = - \left( \frac{\partial u}{\partial x} \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} \frac{\partial u}{\partial y} + \frac{\partial u}{\partial z} \frac{\partial u}{\partial z} \right). \] (50)

Or \( \frac{\partial u}{\partial \tau} = a_1 \frac{\partial^2 u}{\partial x^2} + a_2 \frac{\partial^2 u}{\partial y^2} + a_3 \frac{\partial^2 u}{\partial z^2} + 2a_4 \frac{\partial^2 u}{\partial x \partial y} + 2a_5 \frac{\partial^2 u}{\partial x \partial z} + 2a_6 \frac{\partial^2 u}{\partial y \partial z} \] (51)

where \( a_1 = \frac{k_1}{\rho c}, \quad a_2 = \frac{k_2}{\rho c}, \quad a_3 = \frac{k_3}{\rho c}, \quad \text{etc. etc.} \) (52)

By a special choice of co-ordinate axes this
equation can be brought to the simpler form

\[ \frac{\partial u}{\partial \tau} = a \frac{\partial^2 u}{\partial x^2} + b \frac{\partial^2 u}{\partial y^2} + c \frac{\partial^2 u}{\partial z^2} \] (53)

The new axes may be called the principal axes
of conductibility.

If we further imagine the body transformed
by a homogeneous strain, writing

\[ x' = \sqrt{\frac{c_1}{c_2}}, \quad y' = \sqrt{\frac{c_2}{c_3}}, \]

\[ z' = \sqrt{\frac{c_3}{c_1}}. \] (54)

where \( \rho \) may be chosen arbitrarily, we get

\[ \frac{\partial u}{\partial \tau} = a \frac{\partial^2 u}{\partial x'^2} + b \frac{\partial^2 u}{\partial y'^2} + c \frac{\partial^2 u}{\partial z'^2}, \] (55)

which has the same form as for an isotropic
medium. Hence results obtained on the
hypothesis of isotropy can be transformed
on as to be applicable to the more general case.

For instance, the isothermal surfaces due to
a source of heat at the origin are, in the case
of isotropy, the spheres

\[ x^2 + y^2 + z^2 = \text{const.} \] (56)

In the crystalline case they are the ellipsoids

\[ x'^2 + y'^2 + z'^2 = \text{const.} \] (57)

The corresponding investigation for conduction
in two dimensions gives the theory of de
Seurman's classical experiments on conduction
in crystalline plates.

\[ \text{II. i.} \]

HEAT, CONVECTION OF

§ (1) CONVECTION CURRENTS.—The article on
"Heat, Convection of," has been concerned
mainly with the transport of heat through
bodies of which, except for possible
molecular and electronic diffusion, are at
rest relative to each other and to their bound-
ing surfaces. Where such relative motion
occurs and is associated with temperature
gradients, heat is conveyed by the moving
matter and is then said to be transferred by
"Convection." The phenomenon is prac-
tically limited to fluids, and it occurs so readily
in them that, as was shown in the article
on "Heat, Convection of," the main diffi-
variables in the brackets are of zero dimensions. Hence the conclusion is
\[ h = k d V \left( \frac{V d}{e} \right). \]

Clark appears to be a constant for any particular gas (see Table V, article, "Heat, Convection of"), and not to vary greatly from one gas to another, so that for the same gas, or approximately for all gases, the second term of the function becomes a constant, while the first can be written \( V d k \) or \( V d k \) for a cylinder of diameter \( d \) with its long axis perpendicular to the flow. The formula for this latter case then becomes
\[ h = k d V \left( \frac{V d}{e} \right). \]

If now, the rate of heat loss per unit length is plotted against \( V d \), a constant relation should be obtained for all cylinders.

Davis 1 has considered the data, applying to various sizes of cylinder, and tested them in the above manner. He took the conditions of Hughes’s experiments, namely, a cylinder at \( 100^\circ \text{C} \) surrounded by air at \( 15^\circ \text{C} \), and for values of \( V d = 0.03 \) and \( 0.03 \) calculated the heat loss for fine wires, using King's formula and constants. The results are shown in Fig. 1, together with Hughes’s values and some results obtained by Carpenter 2 for 5 cm. steam pipes. It will be seen that the extrapolation of King’s formula gives remarkable agreement with the curve for larger cylinders. The velocities required to give the value \( V d = 50 \) with a thin wire of 0.003 cm. would be too great to allow this extrapolation to be confirmed experimentally.

(v.) Turbulent Flow.—Very little experimental work has been done on the heat loss due to turbulent flow, except in the case of pipes. Osborne Reynolds, 3 dealing generally with the subject, states that convection in this case is due to two causes, namely, natural internal diffusion and the visible eddy motion which mixes the fluid up and continues to bring fresh particles into contact with the surface. He deduces the formula
\[ E = (A + B V) \rho, \]
A and \( B \) being constants and \( V \) and \( \rho \) the velocity and density of the fluid, \( A \) is small, so that \( k \) is approximately proportional to \( V \). Stanton 4 has verified Reynolds’ theory experimentally and finds that \( k \) varies as \( V \), where \( a \) is a little less than unity.

The effect of the change from stream-line motion to turbulence on convection loss does not seem to have been investigated. Russell 5 has obtained theoretically an approximate formula for stream-line motion in a pipe, according to which the convection loss varies as \( \sqrt{V} \). The critical velocity at which eddy motion occurs has been shown by Coleman and Clement 6 to vary directly as the viscosity and inversely as the diameter. It is useful to note that these variables are associated in the same way (i.e., \( V d \)) in Rayleigh’s similitude formula.

§ (3) Conclusions on Forced Convection

(i.) The heat loss by forced convection from a hot surface is proportional to the temperature difference between the surface and the ambient fluid. This has been shown by Boussinesq from hydrodynamical reasoning, by Rayleigh from the principle of similitude, and it is confirmed by a considerable mass of experimental evidence.

(ii.) For stream-line flow the heat loss is a function of the product of velocity and linear dimensions. This has been shown theoretically by Boussinesq and Rayleigh. The work of King on fine wires makes the heat loss proportional to \((Vd + \text{constant})\). The results on larger cylinders, spheres, and flat surfaces are conflicting, some observers finding that the heat loss varies as \( V \) and others that it varies as \( V \).

(iii.) For turbulent flow in pipes the heat loss is proportional to the velocity.

§ (4) Natural Convection

(1.) Early Results.—The gravity currents set up in a fluid in the proximity of a hot object have been investigated both theoretically and experimentally. The first work of importance was that of Dulong and Petit, to whom are due an elaborate series of experiments on the cooling of hot bodies. Their researches, published in 1817, 7 are practically confined to the heat loss from thermometer bulbs surrounded by constant temperature envelopes.

1 Phil. Mag., 1823, X, 592.
4 Phil. Trans., R.S., 1877, ccc. 67.
5 Phil. Mag., 1910, xx. 601.
6 Phil. Trans., R.S., 1863, vol. 45.
By exhaustin the enclosure and observing the rate of cooling of the bulb the heat loss due to radiation was determined. Experiments were made with the same bulb and enclosure when the latter was filled with gas at varying pressures. As a result the following empirical formula was deduced for the convection loss:

\[ h = m(p - 2 g \alpha) \]

where \( m \) is a constant depending on the shape and position of the body, \( p \) the gas pressure, and \( \alpha \) the temperature difference.

The work of Dulong and Petit was supplemented by that of Péclet,\(^1\) on the value of \( m \) for bodies of simple geometrical shapes. He measured the rate of cooling of hollow metal cylinders, spheres, and prisms filled with water. He used bodies ranging from 5 to 30 cm. in diameter and 5 to 80 cm. length. Great care was taken by means of elaborate devices to keep a uniform temperature inside the vessel, and they were placed inside a large water-jacketed cylinder about 80 cm. in diameter and 100 cm. high.

According to Péclet the heat loss by convection is not proportional to the area of the surface but increases more slowly for bodies of fairly large size. Thus for spheres he makes the heat loss proportional to \( (1-778 + 0.13/\alpha) \) and for horizontal cylinders \( (2-005 + 0.038/\alpha) \), where \( \alpha \) is the radius in metres. Formulas are also given for vertical cylinders and vertical walls, the latter being of the form \( a + h/\sqrt{H} \).

(ii.) Lorenz’s Theory. — After Péclet, the heat loss from a vertical surface freely exposed to air was investigated mathematically by Lorenz.\(^2\) He made a number of assumptions regarding the upward air streams in the vicinity of the plate. Thus the temperature of the air on passing the horizontal plane through the lower edge of the plate is supposed to be that of the air at an infinite distance; it is assumed that the air moves from the bottom to the top of the plate at a constant speed and that horizontal currents, which might be due to expansion, are negligible. On this basis Lorenz arrives at the formula

\[ h = 0.1310(\sqrt{H}) \left( \frac{c^2}{\alpha^2} \right) \]

where \( H \) is the height of the plate, \( \alpha \) the temperature difference between the plate and air, the latter being at a temperature \( T \), and \( c, \rho, k, \gamma \) respectively the specific heat, density, conductivity, and viscosity of air, and \( g \) the gravitational constant. The heat loss is expressed in cal. per sq. cm. per second. It will be observed that the exponent of \( \alpha \), namely 1.23, agrees closely with the 1.238 found by Dulong and Petit. The formula gives the heat loss as varying with

\[ (c^2/\alpha^2) \]

height in the ratio 1/1.238 (for a further discussion of “height effect” see § 4 (c) below).

(iii.) Verification. — The experiments of Langmuir\(^3\) on a vertical disc of diameter 19-1 cm. may be referred to. The disc was heated by a resistor element in contact with the black surface and was embedded in a cylinder of larger diameter, consisting of insulating material, the exposed surface of the disc being flush with the insulation. The temperature of the disc was determined by a thermocouple, and the walls required to maintain it at a constant temperature were measured. In order to reduce the radiation to a minimum the flat surface was of highly polished silver, the emission coefficient of which, calculated from Hagen and Ruben’s formula, varied from about 1.7 per cent at 500° C. to 3.5 per cent at 900° C. of that of a black body. By this means the radiation correction, even at 900° C., was kept as low as 20 per cent. The convection loss was found to fit the formula

\[ h = 0.00004660(\sqrt{H}) \]

so that, as regards the dependence of heat loss on temperature difference, Lorenz’s deduction was confirmed. The numerical constant given by his formula, taking \( H \) the average height of the disc to be 15 cm., was 0.0000466.

Seeing that Lorenz’s assumptions only applied for small temperature differences and that he took no account of the temperature of the surface and of the material, it is surprising that his formula holds so well up to 900° C.

Langmuir also investigated the effect of orientation of a flat surface, using the silvered disc above referred to, and found that the heat loss from a flat surface with face upward was slightly greater than from the vertical surface, while the latter was considerably greater than that for a horizontal surface with face downward. The results are shown graphically in Fig. 2. Apparently in all three cases the heat loss varied as \( \alpha^1 \).

Some experiments have also been made at the National Physical Laboratory\(^4\) on large vertical plates. Experimenting, first, with a plate freely exposed to the atmosphere, the convection loss was found to be 0.0003475° calories per sq. cm. per second, which agrees approximately with Langmuir’s value. The plate was made of polished aluminium, 120 cm. square, and the temperature difference varied up to 100° C. The convection transfer across enclosed spaces between vertical plates was also investigated. It was found that, for air spaces

\(^1\) "Trade” de la chaleur, 1860, trms. by Pilling. Von Knoerndal, O., 1904.

\(^2\) Ann. der Phys., 1861, xiii. 582.

of 1.2 cm, and over, the transfer was independent of the thickness and varied as \(0.000024\delta/\). Here \(\delta\) is the temperature difference between the hot and cold plates, and since the temperature of the enclosed air is intermediate between that of the plates it

would be expected that the coefficient would be lower than that for the plate in the open atmosphere in fact, of the order of one-half.

The subdivision of the enclosed space by a horizontal partition into two equal spaces was

Kilgour on thin platinum wires nearly to the melting-point of platinum, found a considerable increase in the exponent of \(\delta\). He used wires ranging in diameter from 0.004 to 0.06 cm. The wires gave rather abnormal coefficients for Callendar’s formula, connecting temperature and resistance, namely 0.0605 for \(a\) and 1.72 for \(b\), as against 0.0609 and 1.50 for the purest platinum. The temperatures of the wires were calculated from the resistance, using the parabolic formula to 1100°C, and from 1100°C to the melting-point a linear formula. It was estimated that the temperatures were obtained for the of 20° at 1000°C, and some 50° at 1750°C. The length of wire used was about 50 cm, and a measurement of the current and of the coil drop, on the length of the wire manifested by current, served to give both the energy supplied to, and the resistance of, the length in question.

For the radiation correction the figures of Launier and Kurlbaum as to the emissivity of platinum at various temperatures were used. For the smallest wire of 0.01 cm diameter the loss by radiation at 1600°C was only 8 per cent of the total loss, while for the largest wire, 0.6 cm, it amounted to 38 per cent. Launier found that for air the exponent of \(\delta\) in the DuBois and Peltier formula increased from 1.24 to 1.53 at 1400°C, and similar increases were found for nitrogen, carbon dioxide, and hydrogen. As a result of the experimental work on wires and flat slab Launier has put forward his “plastic theory,” which seeks to explain in a simple but comprehensive way the phenomena of convection.

It points out that, according to the kinetic theory, the viscosity of a gas increases with the square root of the absolute temperature, and that the thermal conductivity also increases rapidly with temperature, while the driving force of the convection currents, which is proportional to the difference in density between the hot and cold gas, only increases slowly with temperature. He expresses the opinion that there is a stationary film of gas of definite thickness in contact with any hot object at high temperature, and that from convection consists essentially of conduction through this film and can be calculated from the ordinary laws of conduction. Taking into the use of a flat surface, the rate of heat loss per sq. cm. through the film of thickness \(B\) would be given by

$$h = \frac{k}{B} \frac{C}{\delta T}$$

\(k\) is not a constant for the big ranges of temperature in question, and in order to evaluate the integral it is necessary to express \(k\) as a function of \(T\). This is done by using Sutherland’s formula for change of viscosity with temperature as combined with the
The relation between viscosity, specific heat, and conductivity (p. 449) of articles "Heat, Conduction of Heat" in the text, the value of \( \kappa \) at a certain temperature. The value of \( \kappa \) can then be obtained from the experiment on the plane surface. Knowing the ratio at which the number is being heat by conduction through the film, it was found that the temperature gradient at temperature and has a value about to be determined. In the case of large, the thickness of the film depends on the diameter of the air. Means of the assumption that not only the temperature, but also the temperature gradient at the outer edge of the film is the same in all cases, it is to be shown that the diameter of the film and a wire of diameter are related to \( B \), the thickness of the film for a flat surface, by

\[
\frac{d^2w}{dx^2} = \beta R \left( \frac{1}{A} \right) \left( \frac{1}{B} \right)
\]

Lagrange's observations seem to prove that \( b \) for any particular wire is independent of temperature, and the mean of all its observations on wire gave \( B \) 1 ft. The importance of the fact that the diameter of the film is independent of the temperature gradient is remarkable, and as yet no satisfactory explanation is forthcoming. It should be pointed out, however, that the whole theory built up by Lagrange is based on certain deductions as to the change of conductivity of the copper with temperature on which no direct experimental evidence is yet available. Further, the use of a heat unit for indicating the existence of any appreciable shrinkage with the diameter of 1 ft, from a plane surface, that the film cannot, at any rate, be accepted as a literal interpretation of the phenomenon of conduction.

(a) Principle of Skin-film. A new, more forceful conception of the principle of skin-film, such as a tentative application to natural convection. Experiments by Dr. Park have shown how to apply the principle to the case. Taking account of this is similar to that adopted by Prandtl in his hydrodynamical treatment of natural convection, we get

\[
K = B \left( \frac{1}{A} \right) \left( \frac{1}{B} \right)
\]

where \( b, b, \beta, A, \) and \( C \) have the same significance as in \( \varphi \) (8). It should be noted, however, that the use of a heat unit for indicating the existence of any appreciable shrinkage with the diameter of 1 ft from a plane surface, that the film cannot, at any rate, be accepted as a literal interpretation of the phenomenon of conduction.

(b) Principle of Skin-film. A new, more forceful conception of the principle of skin-film, such as a tentative application to natural convection. Experiments by Dr. Park have shown how to apply the principle to the case. Taking account of this is similar to that adopted by Prandtl in his hydrodynamical treatment of natural convection, we get

\[
K = B \left( \frac{1}{A} \right) \left( \frac{1}{B} \right)
\]

where \( b, b, \beta, A, \) and \( C \) have the same significance as in \( \varphi \) (8). It should be noted, however, that the use of a heat unit for indicating the existence of any appreciable shrinkage with the diameter of 1 ft from a plane surface, that the film cannot, at any rate, be accepted as a literal interpretation of the phenomenon of conduction.
practically independent of the height above a limit of about 50 cm. It was found, too, the value of \( n \) in the formula \( h \propto \theta^n \) had a mean of about 1/25, but that it showed a tendency to increase with height—as appears in the following table:

The value of \( n \) for the largest cylinder is nearly \( \frac{1}{2} \). It is interesting to note that, from considerations of Similitude, the index \( \frac{1}{2} \) means that the heat loss per unit area is independent of the height, and, as stated above, experiment has shown this to be the case.

The law of variation of convection loss with height of the air persists up to a certain height, beyond which turbulence sets in. A further series of experiments at the National Physical Laboratory \(^1\) on vertical cylinders, varying from 4 to 15 ft. in height, showed the heat loss per unit area to be

\[ h \propto \theta^{0.25} \cos \theta \]

and since \( C \), the heat capacity per unit volume, is proportionate to the density and therefore to the pressure, we have

\[ h \propto p^{1.25}. \]

This is in fair agreement with Duhem and Petil's experimental value of 0.15 for the index, while if their value of \( n \) is taken (1-23) the agreement is even closer, giving an index of 0-47 instead of 0.5.

The above examples serve to indicate the use which may be made of the principle of Similitude in the treatment of the problems of natural convection.

§ (5) CONCLUSIONS ON NATURAL CONVECTION.—(i) The heat loss from a hot surface is approximately proportional to \( \theta^1 \) where \( \theta \) is the temperature difference between the surface and the ambient fluid.

This law represents with fair accuracy the results obtained experimentally for different shapes of surface and for values of \( \theta \) up to 400° C., and it is in accordance with the mathematical solution given by Lorenz for a vertical surface. For very large surfaces the index shows a tendency to increase.

(ii) The heat loss has been shown experimentally to vary as \( p^{1/2} \) where \( p \) is the pressure of the gas.

Neither this law nor the preceding one can be deduced generally by hydrodynamical reasoning or from the principle of Similitude, but they are mutually consistent with the solutions obtained on these lines.

(iii) Vukot has obtained empirical formulae for the effect of shape and size on the heat loss. For any body of linear dimensions over about 30 cm. the scale effect is unimportant, i.e. the ratio of heat loss per unit area is approximately the same, being about 0-000045 \( \theta^1 \) cal. per sq. cm. per sec. as \( p, n, s \).

HEAT, MECHANICAL EQUIVALENT OF

§ (1) Historical.—The principle of the Conservation of Energy states that in all its forms energy remains a constant quantity, however many transformations it undergoes. In other words, if energy is made to pass from any condition such as that of matter in motion into any other condition such as molecular or electrical energy, the numerical value of the resulting effect depends simply on the quantity of energy so transformed, not on the method of transformation, the materials, time, or any external conditions.
The demonstration of the truth of this principle by experimental evidence has engaged the attention of many investigators during the past eighty years, but the foundations of our belief may be said to have been laid by Newton when he enunciated his third law, "Action and reaction are equal and opposite."

Professor Tait has pointed out that it is a matter for regret that Newton's own explanation of the terms action and reaction have been so little considered and discussed by succeeding generations. There are two entirely distinct senses in which these words may be used. Action in the one sense is a force only, and to this interpretation attention is and has been almost universally directed.

Newton's second interpretation of his third law is of great importance. It is as follows:

"If the activity of an agent he measured by the product of the force into its velocity and if similarly the counter activity of the resistances he measured by the velocities of its several parts, whether these arise from friction, adhesion, cohesion, or acceleration, etc., then activity and counter activity in all combinations of machines will be equal and opposite."

It should be noted that by the velocity Newton meant the component velocity in the direction of the force. This interpretation tells us that the kinetic energy of a system is increased by an amount equal to the work done in producing motion where the only resistance is that due to acceleration. Where the work is done against friction, however, the visible energy of the system suffers decrease. The principle of the conservation of energy, therefore, could not be regarded as established unless it could be shown that the visible energy thus apparently destroyed is properly to the heat developed against friction.

The idea that heat is a form of motion and therefore of energy is an ancient contrivance. Before the time of Newton, Lord Bacon stated that "the only conclusion that he could draw from the whole of his facts is a very general one, viz., that heat is motion."

He based this conclusion on a consideration of several means by which heat is produced or made to appear in bodies: as the combustion of iron, the friction of solid bodies, the collision of flint and steel, etc. In all these examples heat is produced, or made to appear suddenly, in bodies which have not received it in the usual way of communication from others, and the only cause of its production is a mechanical force or impulse or mechanical violence.

Until the beginning of the nineteenth century, however, this pregnant suggestion of Bacon's appears to have attracted little or no attention. Natural philosophers were reticent in their progress by their belief in the theory of caloric. The existence of an imponderable, indestructible fluid termed caloric was practically assumed in all discussions of natural phenomena.

Count Rumford was the first to question publicly the popular caloric theory, when in 1798 he gave an account of his experiments. He placed a hollow gun-muzzle cylinder heaped with a blunt steel burr and observed that after the cylinder had made about a thousand revolutions its temperature had risen from 89° to 130° F., while the cold matter abraded by the friction weighed only 857 grams. "Is it possible," he writes, "that such a quantity of heat as would have caused 8 lbs. of ice-cold water to boil could have been furnished by an inconsiderable quantity of metallic dust merely in consequence of a change in its capacity for heat?"

The Cabalists, however, were not convinced. Even when Rumford proved that the capacity for heat of the solid metal was that of the dust, they said that, although the heat required to change the temperature of equal masses was the same, yet the solid metal contained a greater quantity of heat than the dust.

Rumford answered that if the heat were rubbed out of the material, a fire must come when all its heat would be exhausted, whereas there was no evidence that such was the case. He also proceeded with further experiments in which the metal was immersed in water, and if we work out the results of these experiments we find that 800 foot-pounds of work would raise one pound of water through 1° F. His final argument was as follows:

"In reasoning on this subject we must not forget to consider that most remarkable circumstance, that the source of heat generated by friction in these experiments appeared evidently to be mechanical.

"It is scarcely necessary to add, that anything which any insulated body, or system of bodies, can continue to furnish without limitation cannot possibly be a material substance. It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner in which the heat was excited and communicated in these experiments, except it be motion. Thus, "I am very far from pretending to know how or by what means or mechanical contrivance that particular kind of motion in bodies which has been supposed to constitute heat is excited, continued, and propagated."

Rumford's work was of the highest value. As Professor Tait remarks, it was throughout free from that a priori style of reasoning which had hitherto been so fatal to the progress of natural science. Had Rumford shown that the heat developed by the solution..."
of a powder in a vessel was equal to that developed by the evaporation of the same mass of the solid, he could have claimed the sole credit of having established the doctrine of the non-materiability of heat.1

Almost immediately after the publication of Fahrenheit's paper, Sir Humphry Davy proved experimentally that two pieces of ice may be melted by rubbing them together, and that it may be conclusive proof (although there is evidence to the contrary at the time that he did not notice it) that heat is not a form of matter, and therefore his experiments are historically of the first importance. In a second series of experiments he ascertained that the friction between the lungs of ice took place in the exhausted vessel of an air-pump. He says:

From this experiment it is evident that ice by friction converts into water, and according to the assumption its capacity is doubled: but it is a well-known fact that the capacity of water for heat is much greater than that of ice, and we must have an absolute quantity of heat added to it before it was converted into water. Friction, consequently, does not diminish the capacity of heat by itself.

It was not, however, till 1812 that he enunciated this proposition: "The immediate cause of the phenomenon of heat then is motion, and the law of its communication is precisely the same as the law of the communication of motion." 2 And, as a reflection, it seems extraordinary that the publication of the work of Rankine and Davy produced so little effect, and that the conclusions should have been regarded merely as an ingenious hypothesis until the time of Joule.

It would be impossible in any historical summary, however brief, to omit the name of Dr. John Mayer (1812), as he was the first to employ the phrase, the mechanical equivalent of heat, and thus enunciate in a distinct form the law of the Conservation of Energy.3

It is doubtful, however, if Mayer has deserved all the credit which was, or is, or may be, assigned to him. The data upon which his conclusions were based were not sufficient, while a great number of his conclusions were misleading erroneous. Mayer derived on more than one occasion that heat depended on motion, and yet has been called by some "the discoverer of the modern theory of heat." Nevertheless, he so much improved, indeed, is the cause of science by his work, although perhaps more likely, as one of the most important of the highest importance in this case, as we and consequences ensued from the premature publication, for the work of Joule and Colding (who partially accomplished an adequate and complete experimental evidence of the truth of the proposition advanced by Mayer.)4

§ (3) Joule's Work. The position at the time of the advent of Joule may be summarised as follows:

Although not generally apprehended, the principle of the Conservation of Energy had, in its main features, been enunciated by Newton. Rankine and Davy had demonstrated that heat is not matter; but their conclusion was not generally accepted. The school of Cabriani still existed, and although the general principle of Conservation of Energy had been enunciated by Mayer, his data were no scanty, and often erroneous, that his conclusions caused but little conviction to men of science. What the situation demanded was rigorous experimental proof that Apparent dissatisfaction of energy, when work was done against friction, was invariably accompanied by the generation of a proportional amount of heat, and that this quantity of heat was independent of the manner in which the work was done, or the nature of the materials employed. Hence the singular importance of Joule's experiments.

The actual numerical values obtained by him are, we now know, somewhat inaccurate, but, at the same time, exactly near the truth. Joule, in 1842, was the first to make an extensive and exhaustive study of the subject, and to demonstrate, as far as his time and means permitted, that heat is a function of the mechanical energy, and that it is independent of the nature of the material.

As a result of his experiments, Joule's data, and the experimental results of Joule's experiments, Table I, and Table II, give the results of the chief determinations from 1842 to 1899 of the Mechanical Equivalent, i.e., the amount of unit of work required to raise 1 gramme of water 1°C.

The values are all given in kilogrammes and therefore no exact comparison is possible unless the values of g be known at each place where the observations were conducted.

If the English units are multiplied by 18.421 - 10 and the French by 0.10001, the result will give the values in cgs with a sufficiently close approximation for the purposes of a rough comparison, for it must be remembered that the temperatures of water differ considerably, as also the mean temperature of the range investigated.5

2 Elements of Chemical Philosophy, 1813, pp. 168-95.
4 See Phil. Mag. 1841, 1, 151.
5 Since the heat required to raise 1 gramme of water 1°C, depends somewhat on the temperature of the water, this must be specified before any exact comparison is possible (see 17).

*Proper's Theory of Heat, with the exception of experiments completed since 1860.

Those who may wish for further information concerning the work of other observers mentioned in Tables I and II, should consult the summary given by Professor Ames in the 'Histoire de l'Association des Congress.***
HEAT, MECHANICAL EQUIVALENT OF

The mean of the values given in Table I = 429.1.
The mean of the values given in Table II = 423.16.
Mean of all = 427.16.
The extreme values are 388 and 488 kilogramme-metres.
It is evident that no certain conclusion can be drawn from values differing to so great an extent. The only safe procedure is that of selection. In making such a selection we should be guided by the answer to the following questions:

(a) Are the temperature determinations sufficiently accurate? The answer will lead to wholesale rejection, especially in the earlier experiments.
The difficulty and importance of temperature measurements were not sufficiently appreciated until within very recent times, and, unfortunately, an error in thermometry is, as a rule, a fatal one; for each thermometer has its own peculiarities and special cause of error; thus, no later increase in knowledge enables us to correct results unless the actual thermometers have been preserved and the conditions under which they were used fully recorded.

Fortunately in two of the most important cases (viz. Joule's and Rowland's) the thermometers actually used have been preserved.

In the former, however, our information is not complete, for we are not sufficiently acquainted with the exact conditions under which their readings were observed by Joule. In the latter, a restandardisation has been accomplished under Rowland's own direction, and thus the corrections can here be applied with far greater certainty. In both cases, as will be shown later, the results as originally published have, in consequence, undergone modifications which from our modern standpoint are considerable.

(b) Has the author given sufficient data to enable us to judge the probable accuracy of all the various measurements involved by his method of experiment?

In this respect, also, the earlier determinations are at a disadvantage as compared with the later ones, for the importance of full information concerning the details of physical measurement has only been generally recognised in recent times.

(c) Are we certain that the energy of the bodies under observation has undergone no modification during the experiment in consequence of molecular changes?

If we could accurately determine both the kinetic energy expended in hammering a nail and also the heat developed, it is not certain that the resulting value of the constant would be correct; for the condition as regards density, strain, etc., of the nail (and possibly of the hammer-head) might have undergone alteration and, in consequence of new molecular conditions, have gained, or lost, in energy.

Now, we know that no permanent altering strain can exist in a nail, and if the external pressure is unaltered, the density will have undergone no change except that due to change of temperature. Hence, conclusions drawn from observation of work expended in heating a liquid are, ceteris paribus, of leading importance.

It is not necessary to enter into further details of the considerations which have led to the selection of the experiments which are about to be discussed. Sufficient it is to say that a careful study of the writings of most of these authors who are mentioned in these tables has led to the selection from Table I. of the work of Joule, Rowland, and Reynolds and Morley, and from Table II. the determinations of Griffiths, Schuster and Gannon, and Callendar and Barnes.

The results obtained by Rowland, after the revision of his thermometers should be considered as of leading importance in the estimation of the numerical value of the constant; while the indirect methods of Griffiths, and above all of Callendar and Barnes, enable us to trace the changes in the capacity for heat of water, and thus render it possible to make a comparison of the values obtained by the different observers.

If their results are expressed in gravitational units a comparison thereof is rendered difficult in the absence of knowledge as to the local value of g. Throughout the remainder of this article (with the exception of the final conclusions) the values will be given in the C.G.S. system, and the mechanical work done expressed in ergs or its multiple the joule (1 Joule = 10^7 ergs).

A further advantage of this method of measurement is that we can express in the same units the work done by an electrical current or by mechanical means. If our electrical units are correct, then when the ends of a conductor whose resistance is 1 ohm are maintained at a potential difference of 1 volt, the work done per second by the current must be 10^7 ergs. Hence, if J be the constant giving the relation between the work done (in joules) and the heat developed (i.e. the mechanical equivalent), then J=10^7H, when H is the number of thermal grammes C, developed per second.

By whatever method the work is done, the Mechanical Equivalent expressed in this scale is the number of Joules required to raise 1 gramme of water through 1° C. Hence this number will also represent the capacity for heat of water at a given temperature, and the phrases "the Mechanical Equivalent" and "the capacity for heat of water" are transferable.

VOL. I
HEAT, MECHANICAL EQUIVALENT OF

Whatever method of determination is adopted, the experimenter has two distinct sets of measurements to perform:

1. The accurate determination in ergs of the change in the mechanical system;

2. The measurement of the quantity of heat generated by the complete conversion of that number of ergs into the form of heat.

It is in the second of these measurements that the chief difficulties have presented themselves.

The measurement of the quantity of heat by the rise in temperature of a known mass of water is the method which has been almost universally adopted from the time that calorimetry became a branch of science. The choice is an unfortunate one, for not only is the accurate measurement of temperature amongst the most difficult of all measurements, but also the material selected, viz. water, is apparently capricious in its behaviour.

Another method is by observation of the quantity of heat required to change the physical condition of a body, as, for example, a given mass of ice. The latter is one which possesses the great advantage that it is independent of temperature measurements. Unfortunately, however, the density of ice cannot be regarded as invariable, and the magnitude of the unit thus obtained is in some respects inconvenient.1

Whatever method is adopted, it should be borne in mind that the true primary unit is the heat equivalent of one erg.

In order that the weight of the evidence in favour of the final conclusion may be rightly estimated, it is advisable to study in some detail the works of the selected observers above referred to.

§ (4) DIRECT EXPERIMENTS. (1) Joule.2

The mechanical method finally adopted by Joule in 1878 consisted in stirring water by means of a paddle which was rapidly turned by hand-wheels, shown at d and e (Fig. 1); the vessel was suspended by a vertical shaft b, which also carried a large fly-wheel f. The mass of the water and the water-equivalent of the calorimeter were carefully determined, the rise in temperature was noted on a mercury-in-glass thermometer, and the work consumed in heating the water was measured by a dynamometer, which consisted of an arrangement for balancing the moment acting on the suspended calorimeter (owing to the rotation of the paddle) by a moment produced by the tension of the cords fastened tangentially to the calorimeter. The cords passed over pulleys and supported weights k. If this moment is constant and is called M, and if the number of revolutions per second of the paddle is N, the work done per second is 2πkN.

In order to reduce the metallic friction as far as possible, the base of the calorimeter rested on a hydraulic supporter, which consisted of two concentric vessels r and s, the space between them being filled with water. The three uprights attached to s press on the base of the calorimeter at t, reduced the pressure on the bearing at 0 nearly to zero.

Joule's calorimeter had a water equivalent of 313-7 grammes of water at 16-5° C.; the mass of water used in an experiment was about 5124 grammes, each experiment lasted 41 minutes, and the observed rise in temperature was about 2-8° C. The mean of his results gave 772-45 foot-pounds at Manchester, as the quantity of work required to raise the temperature of one pound of water 1 degree R. on his mercury-in-glass scale at 61-49° F. Changing to the centigrade scale and to the C.G.S. system, Joule's result may be stated as follows: the quantity of work required to raise the temperature of 1 gramme of water 1 degree centigrade on his mercury-in-glass thermometer at 16-5° is 4-167 x 10⁸ ergs.

In 1895 Professor Sclater3 compared Joule's thermometer with a Tammann thermometer which had been standardised in terms of the nitrogen thermometer of the Bureau International at Sèvres; and in this way was able to recalculate Joule's value for the mechanical equivalent, Rowland also, when reviewing this experiment of Joule's, called attention to certain errors in the determination.

HEAT, MECHANICAL EQUIVALENT OF

ML. Chapolet and Guillouche of the Bureau International, and the scale of his air-thermometer in terms of other thermometers used by later observers was not known. In 1897, therefore, a series of comparisons was undertaken at the Johns Hopkins University between Rowland's thermometers, three Tarnelot mercury thermometers standardized at the Bureau International, and a Cailletet-Griffin platinum thermometer. The result has been a recalculation of Rowland's figures. In the following table the values for the specific heat are given as Rowland first published them, and as recalculated by Day,¹ and by Waidner and Malley.²

Professor Pernet has also endeavored to recalibrate Rowland's values from a careful study of Hamlin thermometers of the same glass and construction as those of Rowland. His figures are almost exactly 1 part in 400 less than those determined by Day and by Waidner and Malley, and in such a case as this one they have the greater confidence in the direct comparisons.

Rowland took pains to vary all the conditions of his experiments as much as possible, running his engines at different speeds, using different thermometers, carrying his observations over different ranges and making in all thirty series of observations. Therefore great weight must be given to his determinations. The only criticisms that can be made are that the range of 10 degrees is too large if the capacity for heat at the mean temperature is desired, and that the radiation correction is uncertain at and above 30°. As Rowland himself says: "The error due to radiation is nearly neutralized, at least between 0° and 30°, by using the jacket at different temperatures. There may be an error of a small amount at that point (30°) in the direction of making the mechanical equivalent too great, and the specific heat may keep on decreasing to over 40°."

Professor Ames' criticism on this work is as follows:

Rowland estimates his possible error at less than 2 parts in 1000; and, now that his thermometric readings have been recalculated, the possible error is clearly reduced to less than 1 part in 1000, unless as a constant or systematic error, which is improbable. Rowland's method of making

thermometric readings is one which is liable to serious error, and it is possible that in the recalculations made by Day, and by Waidner and Malley, the thermometers were not used in identically the same manner as they were originally. There is no obvious reason, however, for believing, as Pernet does, that there is a systematic error in Rowland's research.

(iii.) Reynolds and Morony.⁵—The experiments of Reynolds and Morony are also examples of physical work of the higher order. In 1897 they published an account of their determinations of the mean specific heat of water between 0° and 100° C. The apparatus used was of such a nature that it is not possible to convey, in a brief description, any clear idea of the machinery and its connections; therefore attention will only be called to the manner in which the work was controlled and estimated. The general idea is that of a hydraulic brake attached

![FIG. 4.—This figure shows the Hydraulie Brake mounted with cotton-wood covered by brass, the brake projecting from it towards the left.](image)

The water enters the brake at, or near, 0° C. and runs through it at such a rate that it issues at, or near, 100° C., the work expended on the water being estimated by means of a dynamometer consisting of a lever and weights fastened to the brake. The whole of the work done being absorbed by the agitation of the water in the brake, the moment of resistance of the brake at any speed in a definite function of the quantity of water in it. Except for this moment the unbalanced brake is balanced on the shaft, the load being suspended on the brake lever at a distance of 4 feet from the axis of the shaft. If the moment of resistance of the brake exceeds the moment of this load the lever rises, and vice versa. By making this lever actuate the valve which regulates the discharge from the brake, the quantity of water is

continually regulated in that which is just
required to support the load with the lever
horizontal, and thus a constant moment of
resistance is maintained whatever the speed
of the engines.

In order to eliminate as many errors as
possible, three "heavy trials" were made in
succession, followed by three "light trials,"
touch trial lasting 60 minutes, and the difference
by the two cases, "heavy" and "light," of
1,500 "mean work per trial" and the difference
of the "mean heat per trial" were taken as
"equivalent.

In a "heavy trial," the dynamometer was
adjusted to a moment of 1220 foot-pounds,
and the quantity of water run through in the
60 minutes was about 360 pounds; in a
"light trial" the moment was generally
600 foot-pounds, and the quantity of water run through in the 60 minutes was about 475 pounds, although six trials were made with the moment at 400 foot-pounds. As it
was only necessary to determine temperatures
in the neighborhood of 0° and 100° C., the
results are almost independent of the
nature of the temperature scale, as all tempera-
ture scales must be in agreement at the two
standardizing points, while the temperature
range was so great that an error in actual
elevation at either end of it would have but a
small effect. Again, the long scale on which the
experiments were conducted would tend
to diminish the effect of inaccuracies in the
measurements of the thermal loss by radiation,
etc. The most minute attention was paid to all possible causes of inaccuracy and
there is no apparent constant source of error
in the final results.

When their value is expressed in ergs, it
becomes 4,183 x 10⁷; that is, the mean
capacity for heat of unit mass of water between
0° and 100° C. is 4,183 x 10⁷.

Unfortunately the work of Reynolds and Moorby
does not afford us much assistance in our efforts to
determine the actual value of the heat equivalent.
Assuming the validity of their conclusions, we know
how many ergs (or primary units) are required to
raise the temperature of 1 gramme of water from 0°
to 100°; but we are unable to compare their results
with the values obtained by Rowland and Rowland,
unless we know the relation of the mean thermal unit
over the range 0° to 100° to the thermal unit at the
temperatures covered by the experiments of those
observers. It is quite certain that the number of
primary units required to raise 1 gramme of water
through 1° at different temperatures is not the same;
and it is impossible in the present state of our know-
ledge to ascertain if Reynolds and Moorby's results
are coincident with those obtained by other
investigators.

On the other hand, if we assume the validity of the
results obtained by Reynolds and Moorby, and
compare it with the numbers given by Rowland, we
can find the value of the mean thermal unit in terms of
a thermal unit at some definite temperature;
known strength was applied to the latter. The resistance of the wire was then measured at a known temperature and its temperature coefficient was also measured; therefore, when in the course of a heating experiment the temperature of the water was read, the resistance of the wire could be calculated. Griffiths found also that most rapid and thorough stirring of the water was necessary in order to secure consistent or satisfactory results. He designed a most efficient stirrer which made about 2000 revolutions per minute, the rise in temperature produced by the stirrer alone being in some cases equivalent to 10 per cent of the whole work spent in raising the temperature. The necessary correction, owing to this, was ascertained by a series of preliminary experiments.

3 Griffiths' apparatus (Fig. 6) consisted of a platinum wire (diameter 0.001 in. (0.010 cm.), length 13 ft. (39 cm.), resistance about 0 ohms) cased inside a cylindrical calorimeter, 8 cm. in height and 8 cm. diameter, whose water-equivalent was 85. This wire was heated by means of a current from storage cells. The terminals of the wire were maintained at a constant difference of potential by balancing against sets of Clark cells; and, while the temperature of the water contained in the calorimeter was raised from 14° to 20° C., the time varying from forty to eighty minutes, observations of the temperature and time were made every degree. The E.M.F. used varied from that of three to six Clark cells. Experiments were made using different quantities of water; and by taking differences in the energy and the heat produced in the different sets, many errors were eliminated, and the water equivalent of the calorimeter disappeared from the equation. In the end, therefore, the method depended on the introduction of 120 grams of water into the calorimeter, this being the difference between the quantities used in two trials.

3 Griffiths measured his E.M.F. in terms of the Cavenish standard Clark cell; his resistance in terms of the 'H.A. Ohm' as defined in 1883; his time by a 'rated' chronometer; and his temperature by a Hiele's mercury thermometer which had been compared with a Callendar-Giffiths platinum thermomenter and also with a Thomson's thermometer standardized at the Bureau International. In accordance with the work of Cheesewright and Skinner he assumed the E.M.F. of the Clark cell at 15° C. to be 1.344 volts, and its temperature coefficient to be 1.00077 (15° - 0).

Later, Selmiater called attention to an error of omission in the capacity for heat of the displaced air, but this was neutralized by the fact that there was a slight probable error discovered in the estimation of the E.M.F. of the Clark cells used by Griffiths, reducing the value to 1.342 volts at 15° C.

Hence Griffiths' final values are:

15° C. nitrogen scale: 4.188 x 10^7 ergs.

20° C. " " " 4.192 x 10^7 "

25° C. " " " 4.187 x 10^7 "

In criticism of the method, it may be said that using as small quantities of water as Griffiths did, always practically under the same external conditions, there is more opportunity than should be for systematic errors and for errors due to radiation corrections. In this connection reference must be made to criticisms by Selmiater and to the reply by Griffiths.

It will be seen from this summary that

1 *Phil. Trans., Roy. Soc. A, 1895, cxxxxvi.*

2 *Phil. Mag., 1895, xl.*

3 *Phil. Trans. A, 1896, cxv.*

4 *Phil. Mag., 1896, pp. 451-454.*
Professor Ames that the results of Griffiths' work lead to the conclusion that (assuming the value of $J$ obtained from Rowland's revised experiments) there is at all events no error exceeding 1 in 1000 in the value of our electrical units; but that there is an indication of a possible error of some such magnitude in the electro-chemical equivalent of silver, or in the E.M.F. of the Clark cell, an indication which (as we shall see later) is strengthened by the work of Schuster and Gannon, Kahlé, Patterson and Guthrie.

A comparison of the curves resulting from Rowland's work and Griffiths' proved that they could not both be correct in their thermometry, and this of course excited suspicion as to any conclusions regarding the value of the electrical units. The revision of Rowland's thermometry was partly due to this discrepancy, and the double restandardisations by different methods were, as we have seen (Chap. II. supra), in agreement with each other, while the resulting corrections caused Rowland's curve of the changes in capacity for heat to be almost parallel with Griffiths' over the range of his experiments. This parallelism did not mean that the value of $J$, obtained by the assumption of the validity of the electrical units, was consistent with Rowland's, but that their remaining differences were probably due to the nature of the calorimetric determinations, or to some hitherto undiscovered error in the system of electrical measurements.

(ii.) Schuster and Gannon, 1896.—These observers also measured the heat developed by an electric current when overcoming resistance; but in this case the work was estimated by observation of $E$ and $C$, the latter by the use of a silver voltameter (see Fig. 7). The rise in temperature was determined by a Rankin mercury thermometer, which was compared directly with a Trunck thermometer standardized at the Bureau International. The calorimeter had a water-equivalent of 27 and the mass of water used was about 1614 grammes. The heated wire was of platinum, 760 cm. long and of about 31 ohms resistance. The E.M.F. was produced by storage cells, and was constantly balanced against twenty Clark cells. The resulting current was in the neighbourhood of 0-0 a.mperes, and passed in series through a silver voltameter consisting of a silver plate and a platinum bowl 0 cm. in diameter and 4 cm. deep, whose weight was approximately 64 grammes. An experiment lasted ten minutes, during which about 0-50 grammes of silver was deposited, and the temperature of the water was raised about 2° C. All experiments were performed in the neighbourhood of 19° C. The final result is the mean of six experiments which agree closely with each other.

The result of their investigation gives—

'Capacity for heat of water at 19-1° C. on nitrogen scale = 4-189 x 10'' ergs.'

These experiments were conducted with the skill and accuracy which we necessarily associate with the name of Professor Schuster: "Nevertheless" (to quote Professor Ames again), "there are several criticisms which may be offered to this research. There was only one voltameter used throughout, and none of the conditions were varied. The radiation corrections were most carefully considered, but no details are given of the stirring or of any correction for it. Griffiths in his investigation insists strongly on the need of thorough, not to say violent, stirring.

"These facts make the final result uncertain to an extent which it is difficult to estimate, but which probably is not large. It, as seems probable from the work of Kahlé and Patterson and Guthrie, the electro-equivalent of silver is 0-00111, instead of 0-00118. Schuster and Gannon's value for the specific heat at 19-1° becomes 4-189 x 10''; and, if a consequent error of one part in a thousand is made in the assumed value of the E.M.F. of their Clark cell, the corrected result is 4-185 x 10''."

Certain other possible sources of slight inaccuracy present themselves. The form of silver adopted

---

1 This is not borne out by the later determinations of the electro-chemical equivalent. The value 0-00118 is now adopted.
was a plunging one and the calorimeter was not tight. It is probable that the correction for the latent heat of evaporation during a rise of temperature exceeding 2° C. might be appreciable. The authors refer to this matter as follows: "Evaporation will produce a certain amount of cooling of the calorimeter, if that is not perfectly enclosed; but unless the rate of evaporation changes with the temperature, the effect will only be a lowering of temperature by a constant quantity. The rate of cooling can only be affected by evaporation in so far as it increases with the temperature, and since for small changes it would vary as a linear function of the through a fine tube is heated by a steady electric current through a central conductor of platinum. The steady difference of temperature between the inflowing and outflowing water is observed by means of a differential pair of platinum thermometers at either end. The bulbs of these thermometers are surrounded by thick copper tubes which, by their conductivity, serve at once to equilibrate the temperature, and to prevent the generation of heat by the current in the immediate neighbourhood of the bulbs of the thermometers.

The leads CC serve for the introduction of the current, and the leads PP, which are carefully insulated, for the measurement of the difference of potential on the central conductor. The flow-tube is constructed of glass, and is sealed at each end, at some distance beyond the bulbs of the thermometers, into a glass vacuum jacket, the function of which is to diminish as much as possible the external loss of heat. The whole is enclosed in an external copper jacket (not shown in the figure), containing water in rapid circulation at a constant temperature maintained by means of a very delicate electric regulator.

Neglecting small corrections, the general equation of the method may be stated in the following form:

\[
E_C \equiv \frac{J}{M} \Delta \theta + H.
\]

The difference of potential \( R \) on the central conductor is measured in terms of the Clark cell by means of a very accurately calibrated potentiometer, which serves also to measure the current \( C \) by the observation of the difference of potential on a standard resistance \( R \) included in the circuit.

The Clark cells chiefly employed in this work were of the hermetically sealed type described.
by the authors in the Proc. Roy. Soc., October 1897. They were kept immersed in a regulated water-bath at 15° C., and have maintained their relative differences constant to one or two parts in 100,000 for the last two years.

The standard resistance \( R \) consists of four bare platinum silver wires in parallel wound on mica frames and immersed in oil at a constant temperature. The coils were annealed at a red heat after winding on the

![Diagram of Electrical Connections](image)

**Fig. 9.**—Diagram of the Electrical Connections.

mica, and are not appreciably heated by the passage of the currents employed in the work.

The temperature of the medium was generally about fifteen to twenty minutes, and was recorded automatically on an electric chronograph reading to 0.1 second, on which the seconds were marked by a standard clock.

The difference was probably in all cases accurate to 0.01° C. This order of accuracy could not possibly have been attained with mercury thermometers under the conditions of the experiment.

The external loss of heat \( H \) was very small and regular, owing to the perfection and constancy of the vacuum attainable in the sealed glass jacket. It was determined and eliminated by adjusting the electric current so as to secure the same rise of temperature \( \theta \) for widely different values of the water-flow.

The great advantage of the steady-flow method as compared with the more common method in which a constant mass of water at a uniform temperature is heated in a calorimeter, the temperature of which is changing continuously, is that in the steady-flow method there is practically no change of temperature in any part of the apparatus during the experiment. There is no correction required for the thermal capacity of the calorimeter; the external heat loss is more regular and certain, and there is no question of lag of the thermometers. Another incidental advantage of great importance is that the steadiness of the conditions permits the attainment of the highest degree of accuracy in the instrumental readings.

"In work of this nature it is recognized as being of the utmost importance to be able to detect and eliminate constant errors by varying the conditions of the experiment through as wide a range as possible. In addition to varying the electric current, the water-flow, and the range of temperature it was possible, with comparatively little trouble, to alter the form and resistance of the central conductor, and to change the glass calorimeter for one with a different degree of vacuum, or a different bore for the flow-tube. In all six different calorimeters were employed, and the agreement of the results on reduction afforded a very satisfactory test of the accuracy of the method."

In 1902 Dr. Barnes published a very full study on the subject.

HEAT, MECHANICAL EQUIVALENT OF

The discrepancy between the values given in the above table is, in reality, much less than would appear from a casual inspection. Before coming to any final decision, it is necessary to study the evidence regarding the variation in the capacity for heat of water, and in this connection to consider also such evidence as we possess which is independent of any determinations based upon the transformation of energy. Again, discrepancies arising from the different values assigned to the Clark cell by the observers must be taken into account.

§ (7) THE VARIATION IN THE CAPACITY FOR HEAT OF WATER DUE TO CHANGES IN TEMPERATURE.—Throughout this section, $C_i$ indicates the number of ergs required to raise 1 gramme of water through 1° of the hydrogen scale at a temperature of $F$° C.

The specific heat $c_1$ at any temperature $F$° C. is the ratio $C_i/C_0$, where $C_0$ is some selected standard temperature. It is evident that the value of $c_1$ thus ascertained is not affected by inaccuracies in the magnitude of the electrical units, hence the peculiarity of such methods for the determination of its change consequent on change of temperature. Thus, although electrical methods may be of secondary importance when the object is the determination of the numerical values of $C_0$, they are of primary importance in the attempt to trace changes in the value of $c_1$ consequent on changes of temperature.

Until the publication of Rowland’s work concerning the specific heat of water below 107° C., and these were only made with the view of testing the working of the apparatus, and that Regnault himself attached no importance to them. After discussing his results over the range 107° to 190° C., he stated what would be the nature of the variation between 0° and 100° if deduced by extrapolation of the experimental curve obtained at the higher range.

Boschka discussed Regnault’s experiments, made several small corrections, found an equation which in his opinion closely represented the results over the range 107° to 190°, and then assumed that the expression held good down to 0° C.

It has been necessary to dwell upon this matter, for succeeding investigators who have endeavoured to find the specific heat of various bodies and also the changes therein with change of temperature have, in general, reduced their results to a standard temperature by these extrapolated values. Hence the majority of their conclusions require the revision rendered necessary by our knowledge that the changes in $c_1$ differ both in magnitude and in direction from the changes at higher temperatures. Unfortunately such revision is rarely possible, as the required data are not usually given, for the observer has had such confidence in Regnault’s supposed values that he has considered them unnecessary.

Rowland’s conclusion (1870) that, so far from increasing, the value of $c_1$ decreased with rise of temperature up to about 30° C.

HEAT, MECHANICAL EQUIVALENT OF '101
has been confirmed by the work of Griffiths (range 15° to 27°) and Callendar and Barnes (1° to 99°).

The changes in the specific heat have been determined by Bartoli and Stracciani ¹ and Ledin.² In both cases the conclusions were arrived at by the method of mixtures, and are therefore independent of all energy measurements. Bartoli and Stracciani devoted nearly nine years to their investigation; they not only mixed water with water, but also with mercury and several metals. Their thermometry was based on the standards supplied by the Bureau International, and their results are given in a formula containing the third power of \( t \). They find a minimum about 20°.

In both cases the conclusions were arrived at by the method of mixtures, and are therefore independent of all energy measurements. Jlleroli and Sttieuluti devoted nearly nine years to their investigation; they not only mixed water with water, but also with mercury and several metals. Their thermometry was based on the standards supplied by the International, and their results are given in a formula containing the third power of \( t \). They find a minimum about 20°.

The difficulties of this method are considerable, and a careful examination of their experimental numbers leads to the conclusion that the discrepancies between individual experiments are too great to allow of our attaching much authority to their final values.

The following table summarises the result of the observers above referred to, over the range 0° to 35° of the hydrogen scale:

Values in brackets obtained by extrapolation.

For the purposes of our final reduction of the values of the mechanical equivalent to a common standard, the range from 10° to 25° is of special importance, and the agreement between the values obtained by Rowland, Griffiths, and Callendar and Barnes may be regarded as satisfactory (greatest difference 2 in 10,000), especially when we remember the difference in the methods of experiment, which may be summarised as follows:

Rowland.—Mechanical work done against friction of water, the revised results being dependent on the thermometry of the Bureau International.

For the purposes of our final reduction of the values of the mechanical equivalent to a common standard, the range from 10° to 25° is of special importance, and the agreement between the values obtained by Rowland, Griffiths, and Callendar and Barnes may be regarded as satisfactory (greatest difference 2 in 10,000), especially when we remember the difference in the methods of experiment, which may be summarised as follows:

Rowland.—Mechanical work done against friction of water, the revised results being dependent on the thermometry of the Bureau International.

¹ Rowland.
² Ledin.

For the purposes of comparison with the results of other observers these values have in Col. III. been expressed in terms of \( \sigma_5 \) instead of \( \sigma_{18} \). It appears that Dr. Barnes' temperature scale is that of the constant-pressure air thermometer. Over the range 0° to 100° C. this scale is in close agreement with that of the nitrogen thermometer; the numbers in Col. III. are expressed in the hydrogen scale, the reduction having been effected by the tables given by M. Chappez.

Griffiths.—Work done by an electric current, the data being $E$ and $R$ and the thermometers standardized by platinum thermometers and also by the standards of the Bureau.

Callendar and Barnes.—Electrical methods, data being $E$ and $C$, and the thermometry the differential platinum method.

The methods adopted by Bartoli and Strecchi and Kubh were similar in principle, although differing in detail, hence it might be expected that their results would have been in closer agreement than those obtained by the other observers. Such, however, is not the case. At $10^°$ they differ by 8 parts in 10,000, and at higher ranges by as much as 14 in 10,000.

It appears unlikely that the skill and patience shown by these observers can be executed, and it is probable that the method of mixtures presents peculiar difficulties and uncertainties which are absent in the energy determinations.

These considerations have led to the adoption of the following table for the reductions to some standard temperature:

<table>
<thead>
<tr>
<th>TABLE VII</th>
</tr>
</thead>
<tbody>
<tr>
<td>VALUES OF $\phi$ OVER THE RANGE $10^°$ TO $25^°$ OF THE HYDROGEN THERMOMETERS IN TERMS OF $\phi_{25}$</td>

</table>

The doubt as to the exact conditions under which Joule used his thermometers compels the omission of his value.

§ (8) On the Accuracy of the Values of the Electrical Standards Assumed by the Observers.—Professor Ames 1 in 1900 wrote as follows:

"In regard to the electrical standards, it must be observed that no meaning can be attached to the 'electro-chemical-equivalent' of silver, unless the construction and use of the voltmeter are most carefully specified, and even then there is considerable doubt unless several instruments are used in series.

This fact is well shown in the recent work of Richards, Collins and Heismark at Harvard University, and of Merrill at Johns Hopkins University. The former derive from a comparison of their potentiometer with other forms of instruments that the electro-chemical equivalent with their instrument is 0-0011172 gram per sec. per ampere; while Patterson and Gutho with their instrument find 0-0011103. If, however, the same voltmeter and the same method of use are adopted in the experiments on the electro-chemical-equivalent and in those on the E.M.F. of a Clark cell, the value of the latter is independent of the value assigned to the former. For this reason Kubh's value of the E.M.F. of the standard Clark cells of the Reichsmassstäb (1-5225 volts at $15^°$ C.) is probably correct. The Cavendish Laboratory standard cell has been compared with the German ones; its resulting value is 1-5329 at $15^°$ C., and the later investigations of Patterson and Gutho would reduce this to 1-5327. As Griffiths used the value 1-5342 and as the E.M.F.

It is generally assumed in the equation to the second power, the necessary correction would be almost exactly two parts in one thousand.

For the method used by Schuster and Gannon, where both the E.M.F. and the current are measured, a correction may be accurately applied to the E.M.F., but not to the current, as it is not known what amount of silver one ampere should deposit in their voltmeter; but if we assume that the correction in both cases is in 1000, these results also would be reduced by 2 parts in 1000. The correction assigned is probably in the right direction.

The cells used by Callendar and Barnes have not been compared with those of the Reichsmassstäb, and no 'correction' can be applied with certainty. The figures used above 3 are probably in excess."

Messrs. Ayton, Mather, and Smith in 1905-7 made a careful redermination of the ampere.

The inquiry was conducted at the National Physical Laboratory under the supervision of Sir Richard Glazebrook.

A very perfect form of current weigner was constructed, and the authors wrote: "The current weigner has proved to be the most perfect absolute electrical instrument hitherto constructed, and has enabled us to determine the ampere to a very high degree of accuracy."

The work was conducted with a skill and care

---

1 Exhibition International de Physique, Paris, tome 1.
2 These results were obtained by measurement of RUS, where $E$ was a standard resistance, and it is somewhat difficult to estimate the probable error of the change in the equivalent of silver in the absence of certain knowledge concerning the comparative value of Callendar and Barnes cells, in terms of the Hayleyt volt.
3 I.e., a correction of 2 parts in 1000.
The value obtained by Reynolds and Munro for "the mean thermal unit" was 4-1833 (supra). A study of their tables shows that the actual range was on the average—from about 1°3 to 100° C. An inspection of Table XI shows that the range of variation of $c_1$ is very rapid near 0° C, and a probable value of $c_1|\sigma_{1,2}$ is about 1-008.

</tbody>
</table>

This approximate correction will only raise Reynolds and Munro's value to 4-183. This differs from the mean of the numbers in Col. II by 1 part in 2000. The correspondence is remarkable, and greatly increases the probability of the accuracy of the conclusions at which we have arrived.

The following conclusions may be summarised as follows:

Assuming the Standard Thermal Unit as the energy required to raise 1 gramme of water from 17° to 18° C, on the Paris Hydrogen Scale, or one-fifth the amount required to raise it from 15° to 20° C, on the same scale, then the Standard Thermal Unit = $4-183\times10^8$ Buns.

The value of $c_1|\sigma_{1,2}$ is about 1-008.

### Notes

1 This close correspondence between the value of $c_1$ and the "mean thermal unit" is in many ways a convenience. For example, we are enabled to express the value of thermal measurements obtained by Bunsen's calorimeter in terms of the standard unit, and still with sufficient accuracy, for Professor Michels has shown that the variations in the density of ice sometimes amount to 2 parts in 1000.
Assuming $g = 981$:
1 kilogram-degree $C = 420.6$ kilogrammetres.
1 pound-degree $C = 452.6$ foot-lbs.
1 pound-degree $F = 232.0 = 777.6$ ft.-lbs.

Assuming $g = 981.2$, its value at Greenwich, these values become $426.4$, $1300.5$, $777.5$.

In latitude $45^\circ$, assuming $g = 980.62$, they become $420.7$, $1400.3$, $777.9$.

**APPENDIX I**

The following are the values of the constants which have been employed in the final comparison of the values of $C_{p}$ found by the selected observers.

True sum $= 1.01368$ ft.-lbs.

Electro-equivalent of silver, $= 1.112$ per equivalent.

One degree, 0.00080 at $17^\circ C$.

Weston cell temperature coeff., $E_{w} = 3.45 	imes 10^{\circ} (t-17) - 0.065 	imes 10^{\circ} (t-17)$.

Clerk cell, $C = R = 1.4923$ at $16^\circ C$.

Clerk cell temperature coeff. between $0^\circ$ and $30^\circ C$, $E_{c} = E_{w} - 1.3907 (7 - \circ) - 0.0672 (10 - \circ)$.

**APPENDIX II**

**THE THERMAL UNIT**

Professor Rowlands' views on this matter are expressed in the following letter:

_Town Hall, University, November 18, 1894._

As to the standard for heat measurement, it is to be considered from both a theoretical as well as a practical standpoint.

The ideal theoretical unit would be that quantity of heat necessary to melt one gramme of ice. This is independent of any system of thermometry, and presents to one mind the idea of quantity of heat independent of temperature.

Thus the system of thermometry would have no connection whatever with the heat unit, and the first law of thermodynamics would stand, as it should, entirely independent of the second.

The idea of a quantity of heat at a high temperature being very different from the same quantity at a low temperature, would then be easy and simple. Like-wise we could treat thermodynamics without any reference to temperature until we came to the second law, which would then introduce temperature and the way of measuring it.

From a practical standpoint, however, the unit depending upon the specific heat of water is at present certainly the most convenient. It has been the one mostly used, and its value is well known in terms of energy. Furthermore, the establishment of institutions where it is and thermometers can be compared with a standard, renders the unit very valuable in practice. In other words, this unit is a better practical one at present. I am very sorry this is so, because it is a very poor theoretical unit indeed.

But as we can write our text-books as we please, I suppose that it is best to accept the most practical unit. This I conceive to be the heat required to raise a gramme of water $1^\circ C$, on the hydrogen thermometer at $20^\circ C$.

I take $20^\circ$ because in ordinary thermometry the room is usually about this temperature, and no reduction will be necessary. However, $15^\circ$ would not be inconvenient, or $10^\circ$ to $20^\circ$.

As I write these words I have a feeling that I may be wrong. Why should we continue to teach in our text-books that heat has anything to do with temperature? It is decidedly wrong, and if I ever write a text-book I shall probably use the热 unit, but if I ever write a scientific paper on an experimental nature, I shall probably use the other unit.

HYDRAULICS

I. NATURAL SOURCES OF POWER IN WATER

§ (1) WATER POWER.—During recent years there has taken place throughout the world, a great development in the utilisation of the natural resources of water, and the reasons are not far to seek. On the one hand, there has been a growing consciousness that a plentiful supply of this element is the basis of all sanitary science, and on the other, the necessity of substituting, as a source of power, coal and oil fuels because of their increasing unavailability by the utilisation of water. These two factors have combined to give a special and increasing importance to the question of water supply.

The problem from the point of view of the domestic supply is, of course, not a new one, having engaged the attention of every civilised nation, ancient or modern, but until the nineteenth century it was solved along the line of least resistance and the employment of high pressures was avoided. The needs of the modern city, added to the demands for an adequate supply of water power, have accordingly given a new direction and impetus to the study and practice of Hydraulics.

§ (2) SOURCE OF WATER SUPPLY. (1) Precipitation or Rainfall.—Precipitation, embracing as it does the fall of rain, dew, snow, and hail, is the main source of all water supply, and is usually studied under the general term of rainfall. The supply is derived almost entirely by evaporation from the surfaces of the various oceans and seas which cover the greater part of the earth's surface, and depends upon the radiation from the sun and the capacity of the atmosphere to contain the moisture evaporated. As might be expected, there exist great irregularities in the evaporation, and therefore in the rainfall of large areas. The continuous current of heated air which ascends in the region of the tropics and flows towards the poles carries with it a full complement of moisture and distributes it when temperature and other physical conditions determine.
The precipitation of the moisture in a district varies greatly with its situation, the configuration of the surrounding country, its altitude, and the direction of the prevailing winds. Where the latter are charged with moisture through crossing large tracts of open water the rainfall on the first high ground encountered will naturally be heavy.

On the other hand, the rainfall of a district is small if the prevailing winds traverse a large tract of land and thus become depleted of their moisture. An example is obtained if a straight line be drawn from the east coast of the United States at latitude 35° to a point on the west coast at latitude 45°. the variations of rainfall with longitude being as follows:

The observed rainfall of the North valley above Queensferry affords an excellent illustration of the effect of altitude on precipitation. There the values vary from 28 inches at.

Queensferry (sea-level) to a maximum of 110 inches at a height of 2300 feet above sea-level at the western end of Loch Katrine some 60 miles distant.

These numbers do not represent the extreme precipitation values, which range from practically nothing over the deserts of Africa to as much as 800 inches in the Himalayas. A striking case of unequal distribution of rainfall is supplied by the rainfall of Western India. At Bombay at sea-level the rainfall is about 76 inches; at a station situated on the Western Ghats about 60 miles distant 510 inches was actually measured. Farther west but still on the Deccan plateau at an elevation of nearly 2000 feet the precipitation was only about 20 inches, the wind, deprived of the great belt of its moisture barrier, being then comparatively dry.

(ii.) Annual Variations of Rainfall.—In addition to the very unequal distribution of rainfall from point to point and area to area, great irregularities occur from year to year over the same area.

If over a long series of years a selection is made of the wettest year on record it may be expected to have a rainfall of 51 per cent above the average, while the driest year will be 40 per cent below. There is thus a range between the two equal to 91 per cent of the mean annual rainfall. When the average rainfall of the two consecutive wettest years is taken it will be about 35 per cent above the mean, and that of the two driest 31 per cent below that amount, with a range, therefore, of 66 per cent of the mean rainfall.

If the period be increased to three consecutive years the average for the wettest years will be 1-77 and for the three driest 0-75 of the mean.

Fig. 1, which is taken from the paper read by Sir Alexander R. Binns before the Institution of Civil Engineers in 1892, on "Average Annual Rainfall," shows how the deviation from the mean annual rainfall of the average rainfall over a number of consecutive years diminishes as the included consecutive period increases, until after about thirty-five years it approximates to the total mean value.

From this figure it may be observed that it is possible to have a series, say, of five consecutive years in which the rainfall amounts to only 84 per cent of the mean fall of the district, a circumstance which possesses special significance when calculating the possibilities of the supply of water to be obtained.

(iii.) Seasonal Variations of Rainfall.—In the temperate climates of the British Isles, where the year cannot be divided sharply into dry and wet seasons, the monthly rainfall forms the best means of comparison between one period of the year and another. Fig. 2 has been prepared from the Greenwich records of the years from 1811 to 1891, and shows that February, March, and April have about 10 months of less than 2 in. fall; that January, May, and June are normal months; that the final six months are high months; and that the maximum variation above and below does not exceed 25 per cent of the average monthly value.

The rainfall on the Western Ghats, already mentioned as an instance of irregular distribution over neighbouring areas, is also an excellent example of seasonal variations. The bulk of the rain here falls generally in three periods: the first brief, lasting
perhaps fourteen days, occurs early in June; then the big monsoon from about the middle of July to the middle of August, and the final burst during September and October. During eighty days in all, it has been measured at one of the gauges on these hills about 3000 feet above the sea, the greatest weekly fall being 110 in. Only a few scattered showers amounting on the average to about 3 in. fall during the dry season, which consists of the remaining months of the year.

§ (3) Rain Gauges.—The average rainfall on a catchment area is estimated by rain gauges. It is obviously impossible to construct a rain gauge which shall in all cases catch all the rain that falls. It is however possible, by due regard to the selection of a site, to the method of fixing, and to the proper maintenance of and regular attendance on the ordinary standard gauge, to ensure that valuable information is available concerning the rainfall on a given catchment area. As many gauges as possible must be used, and these situated in places representative of the different elevations and conditions to be met with in the district under investigation. In order that the cycle of variation may be complete it is suggested that gauging should extend over thirty-five years or thereby.

§ (4) Catchment Area.—In estimating the possibilities of a water supply from a certain district it is necessary not only to ascertain the rainfall but also to arrive at the extent of what is known as the catchment area or gathering ground available for the supply. This comprises all the country the drainage of which converges to the point selected as the distributing centre of the supply. The area is usually expressed in acres or in square miles of 640 acres. Its extent may be measured from a topographical map, if such is available, showing the watershed and divides, along which drainage for adjacent areas separate. Otherwise a close approxima-

![Graph](image_url)

**Fig. 2.**

the values obtained as above with a given mean area to determine those for the values determined are multiplied by 

A temperature correction may also be made by

1 See "Meteorological Instruments," Vol. III.
§ (8) GROUND STORAGE.—The undulations of the surface of the drainage area exercise an important influence upon the distribution of the flow. Evidently the storm run-off will be greater from a hilly country than from flat tablelands, and the rainfall remaining available for ground storage will be correspondingly smaller. Then the degree of absorption and run-off largely depend upon the geology of the drainage area, since the porosity of the ground determines its storage capacity. Where a rock ledge is at the surface or crops out in banks the depth of the overlying drift is readily ascertainable, otherwise its extent and character is found by making borings, if practicable, to the rock. Considerable attention has also been paid of late years to the influence of flora and culture on rainfall and flow. Forests and vegetation do not probably affect the total rainfall, but they certainly cause it to fall more uniformly. By protecting the ground from the direct heat of the sun evaporation is retarded, the air immediately overhead is kept cooler, thus increasing its power to condense the moisture in heated and saturated air at a higher level and so steadying the rainfall. Wooded country compares favourably with cultivated land, as the many obstructions to the storm run-off in timbered areas result in a larger proportion finding its way into the ground storage. Then the requirement of moisture for tree growth is considerably less than that of crops, very little surplus being available in the latter case for run-off during the growing season. The effect of the ground storage in equalising the flow is shown by the diagrams of Fig. 3. The measured monthly rainfall in inches is set up from the base AB, and from the resulting curve is subtracted the sum of the estimated evaporation and the measured run-off. Where the final ordinates fall below AB a flow from the ground storage takes place, and where the balance is in favour of the rainfall the ground storage benefits. The lower portion of the diagram represents the variation in the ground storage, saturation being complete during only four months.

§ (9) GAUGING OF STREAM FLOW.—While it is possible, as has been shown, to calculate the total run-off or stream flow from a drainage area from the difference of rainfall and the computed evaporation over that area, the exact determination of the supply available from day to day and month to month can only be obtained by a system of stream gauging. The method adopted will depend upon the volume of water which has to be measured.

(1) Notch Measurements.—When the stream is small, measurement by notch or weir can be made. The weir is generally constructed of planks and the notch is formed in an iron plate screwed to it, and may be either the right-angled triangular type (for small quantities) or rectangular. The weir and face of the notch must be vertical and perpendicular to the direction of the stream, with a clear discharge into the air. If the notch is rectangular the sill must be horizontal and of a length not less than three times the head above the notch measured to still water. Fig. 4 shows the arrangement of a standard sharp-edged weir.

For accurate work measurements of the head taken in a flowing stream are indispensable. To minimise the effect of oscillations of the surface and to avoid the disturbance produced by an immersed object in the stream a well should be made at a sufficient distance behind the weir in the bank of the stream and connected to it by a pipe opening out...
flush with the approach channel and at right angles to the direction of flow. The required head is the height of the surface of the water in this well above the level of the sill or the bottom of the vee.

This height may be conveniently measured by means of an anchored float carrying a scale and rising and falling in contact with a fixed index whose level is known, or carrying an index which moves over a fixed scale. A more exact method is that of the hook gauge shown in Fig. 5.

A hook is attached to the lower end of a divided scale, and its position may be adjusted by means of screw till the point of the hook is just visible at the surface of the water. If the index to the scale has been fixed to show zero when the water is level with the sill, then the head may be read directly on the scale by the aid of a vernier.

(ii.) Rectangular Notch. — For heads above 1 ft., where the bottom and end contractions are free and where the length of event is greater than three times the head, values in close agreement with experiment are given by the formula,

\[ Q = 3.33 \left( b - 0.11 \right) H^2 \text{cub. ft. per sec.} \]

where \( Q \) is the discharge in cubic feet per second, \( H \) is the head in feet, \( b \) the breadth of the notch, and \( n \) is the number of end contractions, the bottom being supposed to be free in every case.

(iii.) Triangular Notch.—Let \( P \) be the head of water above the vertex \( P \) of the notch (Fig. 6). Then assuming the velocity of flow at any depth to be given by \( \sqrt{2gh} \), it is readily be shown that the discharge is

\[ Q = 2.88 \tan \left( \theta/2 \right) H^2 \]

where \( \theta \) is the angle included between the sides of the notch.

(iv.) Right-Angled Notch was found by Professor E. Thomson to have a coefficient \( c \) of the mean value of 0.93 with a variation for a range of heads from 2 to 7 in. of less than 1 per cent, and is the form usually adopted for measuring small quantities. The formula for the discharge over a right-angled vee notch therefore becomes

\[ Q = 2.53H^2 \text{cub. ft. per sec.} \]

§ (10) Velocity of Flow. — For larger streams or rivers the vee is too cumbersome and costly to be used as a temporary measuring contrivance. It is then necessary to obtain the mean velocity of flow which, multiplied by the cross-sectional area of the stream, gives the discharge \( Q \). Experiment shows that the motion at any point in an open channel is never steady and uniform, and that its velocity, if near the surface, may vary by 20 per cent, and if near the bed, by 50 per cent in a short interval of time. This constitutes the difficulty of obtaining the mean velocity with a reasonable degree of accuracy, and the mean of many observations is required. Two methods may be used: floats and current meters.

§ (11) Floats.—These are classified into surface, sub-surface, twin, and velocity rod types, and are illustrated in Fig. 7.

(i.) Surface floats (a) are made of any light material painted to be easily seen, but not projecting more than an inch above the surface in order to minimise the effect of the wind. The wind effect, together with the tendency of the floats to follow any cross-current or surface eddy, render the results obtained very unreliable.

(ii.) Sub-surface floats (b) consist of a small surface float from which a lower float is suspended, the length of connection being adjusted so that the latter may remain at any required depth. In theory the velocity of the lower strain should be indicated, but in practice this is not realised, the relative position of the lower float varying with the direction and velocity of the wind and with the length of connection between the two floats.

(iii.) Twin floats (c) usually consist of two spheres coupled together by means of wire, the lower one weighted so as to float vertically beneath the surface one and as near the bottom as practicable. With this adjustment the velocity of the float will be approximately the mean velocity of the vertical column of water in which the instrument floats.

(iv.) Velocity rods (d) are light wooden rods or tin tubes made in adjustable lengths and weighted at one end with lead strips or wire to float upright, the lower end being as near the bottom as practicable. The velocity of the rod is approximately the same as the mean over its depth and probably gives the more
reliable measurement of the mean velocity of the stream on the vertical in which it floats.

To carry out the operation of gauging by means of floats it is necessary to select a straight stretch of channel of about 200 feet in length, as nearly uniform as possible in section and containing no obstructions. Two cross-sections are ranged out by wires stretched from bank to bank, if the width will allow, and 100 feet apart; these should be perpendicular to the direction of flow. A third line is usually stretched midway between these two. If the observations are to refer to different depths and different distances from the centre of the stream the wires should be divided up into corresponding sections of, say, 10 feet intervals by attaching tags of different colours. The floats are placed in the water about 50 feet above the upstream gauging section, the locus of their passage through the gauging area being noted by line markers and the times of entry and exit recorded. Where the width of channel does not permit of this being done the positions of the floats may be fixed by the use of a telescopelike measuring angles from a base line marked out on the bank.

§ (12) CURRENT METERS.—Current meters may consist of an arrangement whereby the velocity is determined either from the revolutions of a revolving part rotated by the current or by a modification of the Pitot tube.

Typical examples of the former are:

(i.) *Amster current meter*, where the revolving part carries helicoidal vanes mounted on a horizontal axis (Fig. 8), and

(ii.) *Price current meter*, where a series of conical cups is mounted on arms revolving round a vertical axis (Fig. 9).

From the data thus obtained is constructed a rating table showing the relation at a given point between the height of water, referred to some permanent bench mark, and the discharge of the river.

§ (13) CALIBRATION OF METERS IS USUALLY effected by suspending the meter from a travelling carriage, which tows it with a uniform velocity through still water at a depth of about 2 feet. The time over the measured length, and the number of revolutions of the meter, are recorded by means of a chronograph and form a rating table. When in use the meter should be suspended in a similar manner to that adopted during its calibration, as the speed of revolution has been shown to vary with the degree of freedom permitted.

The meter may be used by holding it successively at certain points in a cross-section, or, alternatively, by keeping it in motion during the whole period of its immersion and moving it uniformly from the surface to the bottom of the channel in a series of vertical or diagonal lines. The latter method is not nearly so accurate as the former. Observations taken at points six-tenths or mid-depth in a series of equidistant verticals, the mean velocity in each of these verticals being found by applying a factor, are capable of giving reliable results.

Simultaneously with the velocity observations, soundings should be taken from which the cross-section of the stream can be ascertained.

§ (14) AVERAGE WATER SUPPLY AVAILABLE—Gaugings are not as a rule available over the period of thirty-six years which has been suggested as necessary for complete information, but a ratio between the flow of the stream and the rainfall over the area may be established if one complete year’s record of the former is known. By means of this ratio the flow during a sequence of years may readily be deduced from rainfall records, and the average water supply available be determined.

§ (15) NET WATER SUPPLY.—The reliable procedure is to find the year of lowest annual rainfall during a cycle of, say, fifteen years and to establish the daily flow during this year, comparison being made with the year of actual gaugings on a basis of the effective rainfall, after allowance for evaporation has been made. Alternatively, the general mean annual

1 See § (24) (II).
HYDRAULICS

fall, reduced by 20 per cent, may be taken as the equivalent of the three driest consecutive years, which in practice is the largest amount that can safely be relied upon. A further reduction should be made to allow for evaporation, which in the British Isles may vary from 10 to 20 in., and the remainder, subject to any claims for compensation water to be given off to streams previously supplied by the drainage area, becomes the flow available per annum for a proposed supply.

§ (16) Maximum Continuous Flow.—The most important consideration in any water supply, whatever the purpose for which it is projected, is not the mean annual or daily flow, but the maximum continuous flow, which can under all circumstances be maintained. It is evident that the natural run-off of a drainage or catchment area, subject as it is to continually varying rainfall, evaporation, and ground storage, will itself be of a constantly fluctuating character. If, therefore, the natural flow is to meet all the demands that are to be made upon it, it follows that these demands must be so regulated as never to exceed the minimum evaporation supply of the drainage area which thus becomes the maximum continuous flow of the projected supply. In such a case all flow in excess of this amount becomes of no direct interest to the engineer and must be allowed to go waste.

§ (17) Storage.—If, however, the requirements of the supply necessitate a greater discharge, or if full advantage of the drainage area is to be secured, the water which is in excess during the wet season or during floods must be impounded for use in the dry season. This is done by the manipulation in reservoirs of some of the excess over the low-flow volume during any or all of the periods when it occurs and the utilisation of this stored supply to maintain a continuous flow, higher than the natural low-flow. Storage is usually essential to any extensive supply and is one of its most important features. It assists to still further conserve natural resources by making use of at least a portion of the large and wasting flood waters, and serves to bring them under control, thereby obviating destruction to property and sometimes to life which may otherwise result.

§ (18) Storage Capacity.—The storage capacity which it will be necessary to provide will depend not only on the proportion of flood water compared to the low flow intended to be stored, but will be principally affected by the duration of the longest period of dry weather, which may not necessarily be a period entirely without rain. In this climate, where rainy days are frequent and general, and the soil is always moist or less saturated, the storage provided will depend on the extent of the fall, being greatest where the rainfall is least, and ranges from 120 days' supply in the North of England to twice that amount in the south. In India, where the monsoon forms the principal source of rainfall, and is liable to fail any one year, it is necessary to provide storage to give supply during two consecutive dry seasons.

An excellent example of this is afforded by the Tata Hydro-Electric Power Supply, Bombay, where the total quantity of water required to enable the turbines to give 100,000 h.p. for ten hours daily during nine months, after allowing for loss by evaporation, seepage, and friction in pipes and turbines, is 62,000 million cubic feet, and the combined capacity of the two main storage lakes is about 10,100 million cubic feet. The excess capacity is given in order that balances in years of excessive rainfall may make up for occasional short monsoons.

§ (19) Storage Reservoirs.—Generally speaking, the best site for storage is that where the largest amount of water can be stored by means of the shallowest, shortest, and smallest embankment. If natural lakes can be utilised by the construction of a dam across the efficient river it is usually the most economical method. Notable examples of this are given in connection with the water supplies of Glasgow, Manchester, and Dundee. Otherwise a wide and flat valley with impervious strata, preferably rock and outling in a narrow gorge, should be selected for. The dam for the closing of the outlet to the storage area must be perfectly watertight, and of such a construction as will prevent the impounded water passing below, round the ends, or over the top of the work.

(i.) Earthen Dam.—Formerly the usual type of dam was the earthen embankment, (Fig. 10) with its core of tough, impervious clay or silt-deal or packed with coarse unbroken earth and compacted with proper care. This was backed on either side by hard and less water-tight materials, the inner slopes being covered with stone pitching to prevent the wash of the waves from injuring the earthwork. For embankments of moderate height the inclination of
the surface is usually 3 to 1 on the inner or water side, and 2 to 1 on the outer slope.

(ii.) Masonry Dams. — The earthen dam, when properly constructed, has been very successful, but the tendency in modern practice is to adopt the masonry dam, at least where the height of the wall exceeds 80 feet. The structure may be of coursed masonry, or of concrete mass, or of concrete reinforced by steel, the necessary condition of stability in each case being a continuous rock foundation.

§ (20) OUTLETS. — The outflow of the water under proper control was usually provided for by iron pipes, or stone or brick culverts carried through and under the earthwork of the embankment. Failures have frequently resulted from the leakage of water along the surface of these outlets, or from the fracture of the outlet caused by excessive local pressures or unequal settlement. The latest and best constructed reservoirs have outlets which are entirely disconnected from the embankment, and consist of tunnels or conduits formed of masonry, or reinforced concrete, placed in an adit which has been properly regulated, the line adopted being either round and clear of the end of the embankment or at a considerable depth beneath its lowest point.

For the regulation of the flow the entrance to the culvert or the tunnel is best commanded by a valve tower, which may be provided with sluices on the outside and contain in the interior a spiral pipe connected with the outlet main, and having valves at different levels, so that delivery may take place from near the surface, and therefore be as free from suspended matter as possible.

Siphon outlets are sometimes used where the depth of water does not exceed 27 or 28 feet. The discharge pipe may be carried up the inner slope over the top of the bank and down the outer slope, or it may be laid along the solid ground from the toe of the inner slope round the end of the whole work, as in the case of the tunnel outlet. Valves are necessary, both at the inner and outer ends of the pipe, the latter being at a level sufficiently low to ensure that flow will be maintained against the friction of the pipe. To guard against the accumulation of air at the summit of the pipe, valves suitable for the extirpating of air and the charging the pipe with water must be provided.

§ (21) Settling TANK. — In order to allow for the settlement of sediment and the interception of floating debris a "residuum lodge" or settling tank is formed at the entrance of the storage reservoir. Sluices or valves are provided, so that the discharge from the settling tank may be passed into the reservoir or diverted into a by-channel and thence passed into the waste watercourse. This latter alternative is adopted when it is considered advisable, either because of flood discoloration or similar reasons, to permit the water to pass into storage. A device which effects this automatically is the leaping weir. When the flow is normal the catchwater channel, situated just below and at right angles to the supply stream, collects intermittently and conveys it to the reservoir.

When in flood, the velocity of flow becomes so great that the water misses the collecting channel and passes on to waste (Fig. 11).

§ (22) WASTE WEA. — Since the heaviest floods experienced often occur after a season of rain, when in all probability the reservoir is quite full, it is necessary to arrange for a waste weir to deal with a quantity of water equal at least to the entire flow of the drainage area. In earthen dams it should be kept distinct from the embankment and formed in a cutting in the solid ground at one of its extremities. The flood water carried off should be conveyed by the waste watercourse to the stream bed below in such a manner as not to injure the stability of the structure of the dam. Where the construction is in concrete or masonry the spillway may form part of the wall.

§ (23) FLOW IN PIPES AND OPEN CHANNELS. — In the construction of a distributing system for a proposed supply the important factors to be determined include the volume of water to be passed, the minimum size of pipe or section of channel requisite for its conveyance, and also the conditions involving losses of head and the magnitude of the latter. The choice between pipes and a form of open conduit or tunnel will depend on whether the water is to be conveyed under pressure or not, and largely on the nature of the country to be traversed. Frequently in large works use is made of both methods.

§ (24) VELOCITY OF FLOW IN PIPES. — Many methods have been devised for the measurement of velocity and volume of flow in pipes. The most accurate is that of collecting the discharge during a definite time in a calibrated tank, but this is only suitable when the discharge is small.

(1) Chemical Method. — For low fall installations, where large quantities of water have to be dealt with, use is increasingly being made of the chemical or titration method, in which a given weight per minute of a chemical is introduced into the supply pipe and the quantity present at some point nearer the exit is afterwards determined and the rate of flow deduced. As recently developed this
method is said to give results which are accurate to within 1.5 per cent.

There are also meters of the positive type, where, for example, the filling up of a tank or cylinder is the special feature and the number of revolutions in a definite time are registered on an indicator. Or the volume of water passing through a small turbine may be inferred from the number of revolutions in a given time of its runner after careful calibration by means of the passage of known volumes.

(ii) Pitot Tube.—One of the simplest velocity indicators is the Pitot tube. Its essential feature is a vertical tube \( A \) (Fig. 12) of fine bore with the bottom end and at right angles facing and open to the flow. The height of the column of liquid in the tube is the measure of the pressure equivalent to the velocity head added to the statical head of the tube water outside. To determine the statical head, the tube may be turned through an angle of \( 90^\circ \) about its vertical axis so that its orifice would be parallel to the direction of flow. The illustration shows a second vertical tube \( B \) communicating at the bottom end with the casing, which in turn has openings arranged tangentially to the flow. This serves as a statical head indicator, and the difference in level at any instant between the two tubes serves as a measure of the velocity head, and therefore of the velocity itself (see also article "Aeronautics").

(iii) Venturi Meter.—For measuring large quantities of water the simplest and most satisfactory method is that of the Venturi meter, shown in Fig. 13. It consists of a pipe of area \( A_0 \) uniformly converging to area \( a \), then a short parallel neck afterwards diverging to its full diameter. It forms a section of the main pipe. The whole quantity of water passes through it and there is no obstruction to flow. The difference of pressure which exists at the inlet to the converging length and at the parallel neck, due to the accelerated velocity at the latter point, is measured as in the Pitot tube by a differential gage connected to these points. Then it can be shown that the velocity is given by the equation

\[
V_A = \sqrt{\frac{2g(p_A - p_0)}{W[(A/A_0) - 1]}} \text{ feet per sec.,}
\]

where \( p_A \) and \( p_0 \) are the pressures at the area \( A \) and \( p_0 \) respectively and \( W \) the weight of 1 cubic foot of the liquid, and the discharge in cubic feet per second by

\[
Q = V_A \cdot \Delta A = \Delta A \sqrt{\frac{2g(p_A - p_0)}{W[(A/A_0) - 1]}} = K \sqrt{\frac{p_A - p_0}{W}}
\]

The degree of error which may reasonably be expected is only about 1.5 per cent, and the meter registers efficiently at almost any velocity.

§ 259 Pipe Line Livers.—The losses which occur are due mainly to friction in the pipe, and to friction and eddy formation at entrance and exit, at valves, strainers, elbows, bends, pipe junctions, and at sudden alternations in the cross-sectional area of the pipe. Much experimental work has been undertaken to determine the laws governing the loss of head resulting from resistance to the flow of water through a pipe, as affected by variations in the velocity of flow, the size of the pipes, and by the degree of smoothness of the internal surface.

(i) Early Experiments.—From early experiments it was deduced that the frictional resistance to the flow of a fluid was:

(a) Independent of the fluid pressure per unit of area.

(b) Nearly proportional to the area of the wetted surface, whatever the form of the cross-sectional area of the containing channel, that is, to \( P \), where \( l \) is the length and \( P \) the wetted perimeter.

(c) Approximately proportional to the square of the velocity \( v \) of the fluid.

The frictional resistance \( P \) to the motion of a prism of weight \( m \) through the act of gravity through a distance \( x \) along a channel having a gradient \( i \) given by the ratio \( h/l \), the energy expended will be \( \text{relAx} \cdot h \cdot l \cdot \sin \), where \( h \) is the vertical height between the two ends of the pipe.

This is equal to the work done against friction, and therefore

\[
\text{relAx} = \text{ex} = \cos \theta \text{p} \cdot \text{ex}
\]

Also

\[
\sin \theta \cdot \frac{A}{A_0} = \sqrt{\frac{A}{A_0}} = \sqrt{\frac{A}{A_0}} \cdot \cos \theta
\]

where \( A_0 \) is written for \( A/P \) and \( C_1 (= \cos \theta) \). This is known as the Chezy formula.

The ratio \( A/P \) (area of cross-section/wetted perimeter) is termed the "hydraulic mean
HYDRAULICS

...and the depth of water would have if it were contained in a rectangular channel with a flat bottom of the same area as the wetted surface of the channel. Thus the head \( h \) necessary to maintain a uniform flow \( v \) along a channel of length \( l \) and hydraulic mean depth \( m \) would be represented by

\[
h = v^2 / g \]

The coefficients \( c \) or \( C \), as used in the Chazy formula \( v = C \sqrt{gh} \) given above, can only be constant in the case of pipes if \( h \) is proportional \((1)\) to \( v^2 \) for all values of the velocity and of the pipe diameter, whether large or small, and \((2)\) to the wetted perimeter for pipes of different diameters, and is in addition independent of the roughness of the internal surface.

It is now known that none of these assumptions are warranted, though for a time the compensation of errors obscured the truth. Duhant, Parny, D'Amboisson, and others directed their attention to the true relationship between resistance and velocity, while D'Arey investigated the effects of different diameters of pipes and of varying degrees of roughness, and the investigators in both directions sought to express their results in terms of a binomial function of \( v \).

(ii.) Reynolds' Index Law.—Professor Osborne Reynolds evolved a rational formula based on the assumptions that the resistance to flow varied with the diameter, length, and surface conditions of the pipe; with the viscosity and density of the fluid, and with the mean velocity of flow through the pipe, and that it varied with some power of each of these factors. A modification of this rational formula has been adopted by various later investigators, including Unwin, and is represented by the relation

\[
h = \frac{f}{\pi d^4} \]

where \( h \) as before is the drop of head in feet required to maintain a uniform velocity. The resistance is thus proportional to the 4th power of \( v \) and inversely proportional to the 4th power of the diameter \( d \), while \( f \) is a coefficient deduced along with the values of \( a \) and \( z \) from the results of various experimenters, \(^1\) being in feet.

Unwin's mean values are as follows:

<table>
<thead>
<tr>
<th>Surface</th>
<th>( f )</th>
<th>( a )</th>
<th>( z )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Wrought iron</td>
<td>0.0204</td>
<td>1.210</td>
<td>7.75</td>
</tr>
<tr>
<td>Asphalated pipes</td>
<td>0.024</td>
<td>1.127</td>
<td>13.6</td>
</tr>
<tr>
<td>Riveted wrought iron</td>
<td>0.0216</td>
<td>1.091</td>
<td>13.8</td>
</tr>
<tr>
<td>New cast iron</td>
<td>0.0204</td>
<td>1.108</td>
<td>13.9</td>

</tbody>
</table>

The values of \( f \) and \( a \) increase with the roughness of the surface, and \( z \) varies with the surface and increases with the diameter.

(iii.) Practical Considerations.—In dealing with practical problems, however, it is often convenient to express the relation between the velocity and the head in the form adopted by Chazy,

\[
h = \frac{f}{\pi d^2} \quad \text{or} \quad v = C \sqrt{gh} \]

where \( f/2g \) has been written for the coefficient \( C \), and Professor A. H. Gibson includes, in his "Hydraulics and its Applications," tables of the values of \( f \) and \( C \) calculated from the mean results of the formulae of Unwin, Tutton, and Thrup, showing within the range of velocities common in practice their variation with \( v \) and with the pipe diameter in pipes of different types. The internal corrosion of a pipe, by increasing the roughness of its walls and by reducing its effective area, will usually increase the value of \( f \) considerably after a few years' use, and must be allowed for when estimating the diameter necessary to maintain a given discharge.

(iv.) Loss at Entrance.—This will depend on the form of entrance adopted, the loss of head varying from about \( 0.5 \sqrt{v^2/2g} \) ft. with a bell-mouth to \( v^2/2g \) ft., when the pipe projects into the reservoir and forms a re-entrant mouthpiece. Weisbach has shown that with a gate valve in a circular pipe the loss in head due to the presence of the valve when three-fourths open would be represented by \( 2.2 \sqrt{v^2/2g} \) ft., and at half opening be eight times as great.

(v.) Bends and Rannels.—If loss of head is represented by \( F \sqrt{v^2/2g} \) the following values of \( F \) are approximately correct for losses in pipes of radius \( r \), with heads of radius \( R \), making an angle of \( 90^\circ \):

<table>
<thead>
<tr>
<th>( R/r )</th>
<th>Elbow</th>
<th>4</th>
<th>8</th>
<th>12</th>
<th>16</th>
<th>20</th>
</tr>
</thead>
<tbody>
<tr>
<td>F</td>
<td>1.20</td>
<td>0.4</td>
<td>0.29</td>
<td>0.17</td>
<td>0.10</td>
<td>0.07</td>
</tr>
</tbody>
</table>

(vi.) Loss at Exit.—The whole of the kinetic energy of pipe flow \( v^2/2g \) is usually dissipated in early formation when discharged into another mass of water, and if discharge takes place at a height \( h \) above the free receiving surface this height will be included in the loss of head.

(vii.) Total Loss of Head.—The total head \( H \), therefore required to maintain a uniform velocity of \( v \), will be equal to the kinetic energy at exit, plus the loss by friction in the pipe, plus the losses at entrance, valves, bends, or sudden changes in section of the pipe, and will be represented by an equation such as

\[
H = \frac{v^2}{2g} \left(1 + \frac{f}{\pi d^2} \right)
\]
Hence, 

\[ v^2 = \frac{2gH}{1 + \sum F^2 (f/m)} \]

We obtain thus the velocity due to a given difference of head in a pipe of given length and diameter. Since the discharge in cubic feet per second \( Q = \text{area} \times v = \pi d^2 / 4 \),

we find 

\[ Q = \frac{\pi d^2 \sqrt{2gH}}{4 \sqrt{1 + \sum F^2 (f/m)}} \]

If the length and diameter of the pipe are known, the head necessary to give any required discharge may be determined. Thus:

\[ H = \frac{8Q^2 (1 + \sum F^2 (f/m))}{\pi^2 d^4} \]

§ (26) Hydraulic Gradient.—If steady flow is to be maintained between two points at different levels through a pipe running full with a velocity \( v \), the total difference of level must be equal to the total loss of head. Thus:

\[ \Sigma F (f^2/2g) = H. \]

If a longitudinal section be made along the line of the pipe and, if from a horizontal line drawn through the upper surface there is set down a series of vertical ordinates representing at various cross-sections the total loss of pressure per unit volume from the pipe entrance to each section considered, then the curve formed by joining the ends of these ordinates defines the hydraulic gradient for the pipe line. For a straight length of pipe without valves or other obstructions the gradient would be constant and would be represented by a straight line (Fig. 14). The slope of the curve giving the hydraulic gradient is termed the virtual slope of the pipe.

§ (27) Open Channels.—The formula \( h = (fL^2/2g) \) is generally adopted as a basis for determining the loss of head for a non-accelerated flow in open channels, where \( h = (\Delta \Sigma) = \text{the rule of the cross-sectional area to the wetted perimeter} \). And to maintain constant flow we must have:

\[ v = \sqrt{\frac{2gH}{f/m}} = c \sqrt{\frac{m}{c^2}}. \]

The difficulty has been to determine values of \( f \) or \( c \) which will be applicable to channels having widely differing physical characteristics.

Bain deduced for \( C \) a value given by \( \log 1.5 + (N/\sqrt{m}) \) foot units, where \( N \) is a quantity which varies with the character of the surface. This gives good results for channels under 20 feet wide and with velocities not greater than 4 feet per second.

The value generally used is that derived from the Ganguliet and Kutter formula:

\[ C = 41.0 + (0.0281/3) + (1.8112/N) \] foot units.

\[ 1 + 41.0 + (0.0281/3) (N/\sqrt{m}) \]

FIG. 14.

\( N \), again, depends on the character of the surface. Probably a rational formula of the type:

\[ h = \frac{fL^2}{\Delta \Sigma} = \frac{h}{m^2} \] would most nearly represent the law of channel flow.

Amongst others, Professor C. B. Claxton Emerson determined the values of \( f \), \( m \), and \( C \) for such a formula from the many experimental results available, and a few examples are given below:

1 If the slope of the channel be uniform, then \( e^{l} \) is constant, which we denote by \( e \).
which will give the maximum discharge for a given slope and given cross-sectional area. Now  
Q = \frac{A}{\pi} = C \sqrt{\frac{A^2}{\pi^2} + \frac{\Delta}{\pi^2}}.\] On the assumption that \( C \) is constant for a given surface, in order to  
that \( Q \) should be a maximum we must find  
the differential coefficient of this expression and equate it to zero. The following sections  
give the proportions thus obtained for a few of the common forms of channel and the  
resulting value of \( Q \) on the assumption that  
\( A \) has a constant value.

**Trapezoidal Channels.**—Let \( b \) be the half bottom breadth, \( d \) be the depth, \( \alpha = \tan \beta \), where \( \beta \) is the angle of  
slope of the sides. Then we have

\[
\begin{align*}
A &= 2bd + \frac{b^3}{3} \\
V &= 2(b+d) \sqrt{1 + \frac{d}{b}}
\end{align*}
\]

and remembering that \( A \) is constant we obtain, on substituting in the value \( Q \) from these expressions, as the condition for  
maximum discharge, the result that

\[
Q = \frac{A}{\pi} = C \frac{1}{\sqrt{1 + \frac{d}{b}}}.
\]

and in this case the sides of the channel  
touch at a circle of radius equal to the depth of the  
channel having its centre in the surface.

The maximum discharge in terms of \( b \) and \( \alpha \) becomes

\[
Q = \frac{A}{\pi} \frac{1}{\sqrt{1 + \frac{d}{b}}}.
\]

and for a rectangular section where \( \alpha = 0 \)

\[
Q = A \sqrt{2} \frac{1}{\sqrt{1 + \frac{d}{b}}}.
\]

**Circular Channels**—The hydraulic mean depth  
of any polygonal channel where \( A \) is constant  
is greatest when the sides and bottom of the channel  
are tangential to a circle having its centre in the  
water surface. The semicircular section when  
running full may be regarded as the limiting case,  
and has a hydraulic mean depth of \( d/2 \), which is  
the maximum for properly designed polygonal forms,  
and therefore gives the maximum discharge for a  
fixed area.

**Circular Sections.**—With a circular channel of fixed  
diameter, but where the water-level subtends a varying angle \( \beta \) at the centre, the condition of maximum  
velocity can be shown to be \( \theta - \tan \beta = \pi/2 \),  
and for maximum discharge \( 2\theta = \pi - \beta \); \( \beta = 208^\circ \) satisfies this latter condition.

Tables showing the relative discharges of  
trapezoidal channels with varying slopes, and  
circular channels with different flow levels,  
are given below:

These numbers representing the available power can only be regarded as very approximate, and so far as they relate to this country include much of the supply necessary for domestic purposes, or which must be conserved for trade and commercial purposes. The daily rate of consumption under this heading varies from about 20 gallons per head of population in Sheffield to 70 gallons in Paddington, and provision requires to be made that, in the event of the emergency of fire, the supply per hour may exceed this by as much as 50 per cent.

The total available water supply is for commercial and domestic purposes capable of being supplemented by the use of wells and underground reservoirs, which, however, necessitate the use of pumps, and do not add directly to the power resources of the country.

The following are mentioned as a few typical examples of the largest power installations which have recently been made:

§ (30) Tidal Power.—Perhaps the greatest source of water-power is to be found in the daily motion of the tides of the ocean. Tides are due to the gravitational attraction of the sun and moon, great masses of water become possessed with an energy of position which it is possible to convert into work. While the practicability of such a project is assured, the desirability and expediency becomes entirely a matter of cost. The choice of methods lies between the use of a single tidal basin divided from the sea by a dam in which are placed turbines, having intermittent periods of working separated by more or less lengthy intervals of idleness and equipped with suitable storage plant, and the adoption of a system of duplicate tidal basins capable of working at all states of the tide and therefore without storage plant. There are several options with either method.

(l) Single Tidal Basin.—When a single tidal basin is used, water may be impounded through sluices during the rising tide and, when the sea-level has fallen a portion of its range, allowed to operate the turbines at a nearly constant head until low water. If the curve ABC (Fig. 16) represents the sea-level on a time base, then ab shows the level in the tidal basin, on the supposition that the rate of fall is kept constant and the head is nearly equal to AB throughout. The period of working is represented by a b, and the interval of idleness by the tide period AC, less a b. An increase in the working head can only be obtained by means of shortening the period of operation, and the maximum output will be obtained when the head is approximately half the tidal range. An increase in output may, however, be made by utilising both rising and falling tides, the arrangement of the water passages permitting the use of the turbines with a flow from either side of the wall in which they are set, or duplicate inshore turbines are provided.

Another possible modification is where the water during both rising and falling tides is allowed to flow through the turbines and to adjust its own level. If ABC (Fig. 17) repres
sents the sea-level, the level in the tidal basin would also show a cyclical variation as at $\omega$, the working head being the intercept between the two curves. At their intersection points $ab$ the head is zero, and for an interval before and after these points the turbines will cease to function. The working period and the possible output per tide is greater with this arrangement, but the variation of head, with all its disadvantages, is very large.

(3) Tidal Basins.—When the installation consists of two tidal basins, power may be developed continuously by allowing flow through turbines to the sea to take place from one called the upper basin during the lower portion of the tidal fall, while the other or lower basin is emptying through its sluices. Flow from the sea through the turbine to the latter occurs during the upper portion of the tidal rise, and meanwhile the upper basin is being filled through the sluices. This is shown diagrammatically in Fig. 18. In addition to the cost of providing two tidal basins this method necessitates duplicating turbines, while the output is not larger than in the best of the single-basin systems.

Whichever form is adopted the cost per horse-power will vary, other things being equal, with the tidal range. Because of this, and also because of its favourable configuration, much attention has been given to the estuary of the Severn, the mean range of spring tides at Chepstow having the high value of 42 feet and of neap tides of 21 feet, as compared with the average valve around the coast of Great Britain of 16.1 and 8.4 feet respectively.

It is estimated that if an area of 20 square miles could be utilised at the spring tidal range of the Severn the average daily output working without storage plant would approximate to 10 million horse-power-hours.

The principal difficulty, however, in connection with any tidal-power scheme lies in the relatively great fluctuations in head. The cyclical daily variations may be provided for and continuous operations ensured, but the great relative differences between spring and neap tides force the choice of either designing for the minimum head and thus utilising only a small proportion of the available energy, with a consequent increase of the power unit cost, or of adopting some equally costly form of storage. While this is so the vast possibilities which await the development of tidal power at a reasonable cost makes it imperative that the investigations at present in progress should be continued until success is achieved.

III. AVAILABILITY OF WATER SUPPLIES FOR POWER ON OTHER PURPOSES

§ (31) PUMPS.—In order to utilise directly a supply of water there must be in addition to an adequate quantity an available head capable of being converted into power or used in overcoming resistance during its distribution for domestic, trade, or irrigation purposes. When the supply does not possess the requisite head it can be acquired by the raising of the water from a lower to a higher level by means of a properly designed machine, and is termed Pumping. The power of the machine or pump must be sufficient not only to raise the required amount in a given time but also to overcome the various resistances to flow encountered in the process. These consist principally of the friction of the pump and of the inlet and delivery pipes. The nature and magnitude of the pipe line losses have not yet been dealt with in discussing the loss of head incidental to a gravitational supply. The characteristics, losses, and efficiency of the different types of pumps will now be treated in turn.

§ (32) Screw Wheels, supposed to have been used by the Chinese in very remote times, are still in operation in the Foon district and also in the lowlands of Holland, where large volumes of water have to be lifted to comparatively low heads of 4 to 6 feet. In some of the recent examples they have been capable of dealing with 300 to 400 tons per minute against a head of 5 to 6 feet, the diameter of the wheel being 30 feet by 5 feet wide, and the number of revolutions 6 or 7 per minute. The entrance of the water to the wheel is controlled by a sluice gate which delays the contact of wheel and water until the vane has nearly reached the bottom of their path. The tail sluice may either be adjustable about a horizontal axis at its lower end or fixed to take up a natural position as determined by the discharging stream. The efficiency of the plant including the drive varies from 65 to 75 per cent, depending upon the ratio of the wheel diameter to the lift. Generally speaking, the larger the diameter for a given lift the more efficient is the pump, and the usual proportion is that the diameter is $10 \sqrt{H}$.

§ (33) ARCHIMEDEAN SCREW.—It is fitting in the case of this obsolete type that we have a record of its use in Egypt before Rom's time, so the largest and possibly the last installation of importance should be that at Katabbah in 1881. It consisted of ten sets of screws each designed to raise 25 tons of water per revolution against a total head of 12 feet, which, with a speed of 6 revolutions per minute, represented...
HYDRAULICS

120 h.p. per screw. The plant was not a success and was soon replaced by another type. In the designed arrangement a helical screw rotated about an axis inclined to the horizontal at an angle less than that made by the surface of the helix, and was contained in a closely fitting tube, the lower end being immersed in water. On rotating the screw, the water tended to run down the surface of the helix by reason of its greater inclination and consequently passed up the tube emerging at the top in the head water. Under favourable circumstances an efficiency of 75 per cent has been reached.

§ 94 Reciprocating Pumps. — This important class of pump consists essentially of a cylinder in which the reciprocating motion of a bucket, plunger, or piston, or a combination of these, is used to lift water directly, by the action of suction or of pressure. On the up or suction stroke of the pump a partial vacuum is formed beneath the plunger or piston, and atmospheric pressure acting on the free surface of the supply produces flow in the suction pipe. A volume of water equal to the displacement of the plunger is admitted to the pump chamber through a fast suction valve which on the down stroke closes automatically while an equal volume is transferred to the pressure side of the delivery valve. Where the arrangement includes both bucket B and plunger p, as in Fig. 19, the water displaced on the down stroke passes through lift valves v in bucket, and a volume equal to the displacement volume of the plunger is discharged through D. On the up stroke a discharge equal to the difference of the bucket and plunger displacement volumes takes place.

FIG. 19.

When the pump is of the type shown in Fig. 20, having a piston and plunger, then during the in stroke a volume of water equal to the volume of the piston displacement is passed through the discharge valve D, but a portion of this is simply transferred to the opposite side of the piston. The actual discharge during this stroke is only equal to the plunger displacement volume. On the out stroke the delivery is equal to the difference between the volumes of the piston and plunger displacements. In each case, therefore, the discharge is divided over the two strokes.

FIG. 20.

Let $h_a$ = head of lowest position of plunger above lower water surface.

$h_d$ = head of upper water surface above lowest position of plunger.

$h_p$ = atmospheric pressure head.

$h_f$ = head required to overcome friction of suction pipe.

$h_e$ = head required to produce acceleration of suction water column.

The pressure head available to produce flow in the suction column $=h_a-h_f$ and must be not less than $h_a-h_d$.

If the flow is small $h_a-h_f$ will nearly equal $h_a$, and $h_d$ may nearly equal $h_p$ or 21 feet approximately. In practice $h_a-h_p$ represents a head of about 10 feet, and $h_d$ is not greater than 24 feet.

If A = area of cross-section of bucket or plunger in square feet.

$L$ = length of stroke.

$W$ = weight of cubic foot of water in lbs.

Then $WA_a$ = weight of water displaced during suction stroke through a distance of $L$ feet.

$WA_h$ = weight of water lifted during delivery stroke through a distance of $L$ feet.

Therefore the total work done per cycle $=WA_h(h_a+h_p)\text{ foot-lbs.} = WA_hh_a\text { foot-lbs.}$, where $h_a=h_a+i$ = total lift.

With the bucket type pump, suction and delivery takes place during the up stroke, the return stroke being idle. When a plunger is used suction takes place during up stroke and delivery during return. In either case delivery is intermittent and occurs during alternate strokes. Where a bucket pump is converted into the combined bucket-and-plunger type by the enlargement of the bucket rod the work done per cycle remains the same, but a delivery, equal to the difference of the volumes swept through by bucket and plunger respectively, occurs during the suction
stroke, while the remainder of the bucket volume is discharged during the down stroke. For equal discharges on the two strokes the area $A$ of the piston or bucket should be twice the area $a$ of the rod or plunger.

To equalise the work done during the two strokes of the cycle, when the pump is vertical and the weight of the reciprocating parts is $W_p$, the following relations are necessary:

$$W_p (A - a) h_d + W_s = W_s h_d - W_p$$

and

$$a = \frac{W_p}{W_d} + \frac{A h_d}{2 h_d}$$

§ 35 Single and Double-Acting Pumps. — Where suction takes place during one stroke only of the cycle the pump is said to be single-acting, though the flow is continuous. This type may be converted into the double-acting type by the duplication of suction and delivery valves, so that motion takes place during both in and out strokes of the piston. If the pressure head against which delivery is taking place is high or the water being pumped contains considerable impurities rendering accessibility to packing desirable, the plunger type of pump is usually adopted; and if the pump is double-acting, outside in preference to central packing is employed. This is shown in Fig. 21.

(i) Variations in Discharge. — In pump design it is intended that the volume of water dealt with either in suction or in delivery should just equal the volume of the plunger displacement, and it follows that with passages of uniform section the rate of flow will depend on and vary with the velocity of the plunger.

A, B, C, Fig. 22, shown on a time basis the velocity curve of a plunger driven by an ordinary crank of definite radius, during the down stroke, and will also represent to some scale the varying velocity of the suction water. C, D, E is the corresponding velocity curve during the delivery stroke, and will therefore be a measure of the discharge velocity and for short intervals of time of

$$.Q$$

water, single-acting will vary from zero at $A$ to a maximum at $B$, falling again to zero at $C$ and remaining so during the return stroke. On the delivery side there is no velocity during the period from $A$ to $C$, after which it begins to rise, reaching a maximum at $D$ and thence falling to zero at $E$.

These fluctuations of velocity may be modified by the introduction of a duplicate pump, drawing from the same suction and discharging to the same delivery pipes, but driven by a crank set at an angle of 90° with the first, the resulting velocities being shown by the curve $\Delta A B C H D$.

(ii) Variations of Pressure. — Since the flow in the suction pipe is dependent on the varying velocity of the plunger, the water in that pipe must be subject to fluctuations of pressure following on the varying accelerations necessary to maintain constant. These accelerations in the flow will be proportional to the piston acceleration $a$ at the same instant. When the pump is driven from a shaft rotating with uniform angular velocity of $\omega$ radians per second, by a crank of radius $r$ through a connecting rod of length $l$, the maximum values of the acceleration, which are equal to $a$ to $\omega^2 r (1 \pm \frac{r}{l})$, occur when the piston is at its inner or outer extreme travel positions, that is at the opening of the suction and delivery valves. There must be sufficient force available at these points to produce the required acceleration if flow is to take place and separation of the water column and piston is to be avoided. In addition to the accelerating head $h_a$, there is the force necessary to overcome friction represented by a head $h_f$. In Fig. 23 (a) the

1. See "Rheonetics of Machinery," § 3 (6).
the first instance into the air vessel, and when retardation of the plunger takes place and the delivery column tends to lose contact with it, discharge is supplied from the air vessel.

(iv.) Air-charging Device.—In addition to the proper proportioning of the air vessels arrangements must be made for their being kept adequately charged. The volume of air in the delivery air chamber tends to diminish by being absorbed into the continually changing body of water with which it comes into contact, while the opposite holds good in the suction air chamber. In order to equalize these changes some form of automatic air pump is necessary, and a simple apparatus known as the Wippmann air charger is frequently fitted. It is illustrated in Fig. 24 and consists of a small chamber I connected by a delivery valve d to the air vessel A and by a suction valve k, normally open, to the pump chamber, while a suction valve a is direct-opened to the air.

During the outward stroke of the plunger the pressure in I falls to the suction pressure of the pump and the valve a admits additional air. On the return stroke valve a closes and the delivery valve d opens, admitting a fresh charge to the air vessel, where a relief valve prevents overcharging. If necessary, the air inlet may be connected to the suction air vessel, where surplus air tends to collect, instead of to the atmosphere, and in the usual method when an air pump is used.

(v.) Pump Valves.—The operations of suction and delivery, as they have been described, have implied that the control was by means of automatic valves. It has been assumed that during suction the inlet control was by a valve which opened as a consequence of the displacement of the plunger in one direction and closed immediately on the motion being reversed; also that the outlet control was similar but opposite in action, being closed during the suction stroke by the external pressure of the discharge water and opened during the succeeding stroke by the excess of the pressure in the pump chamber over the pressure head of the delivery column. For low pressures and slow speeds the procedure just described is that which is usually adopted. The valves are made of rubber or vulcanite.
HYDRAULICS

Discs working against a perforated grid. They are returned to their rest by the action of a spring or by reason of their own elasticity aided by the pressure of water above them and are shown in Figs. 25 and 26. In order to withstand the high pressures which have now become common, metallic valves were introduced. Examples of these are the single mitro type shown in Fig. 27 and the double-seated ring valve in Fig. 28. The average number of revolutions for pumps using these types of valves is approximately 60 per minute.

The closing of valves is accompanied by a certain amount of shock, the violence of which depends on the kinetic energy stored in the valve and in the following mass of water at the instant of closing. This will vary as the lift, as the weight, and as the velocity of the valve. All three are functions of the diameter, and the lift to be fully effective should, in the case of a ring single-seated valve, be equal to one-quarter of the diameter. By an increase in the number of valves, the diameter, and therefore the lift, the weight, and the velocity may be reduced. Suitable arrangements are illustrated in Fig. 29, where (a) shows a quadruple-seated mitro ring-valve and (b) a three-tier Boshivo multiplo-valve box.

Where high speeds are necessary for obtaining the required discharge special valves are used which, by their construction, tend to modify the shock resulting from sudden changes in the direction of flow at the valves. Among the most successful of these are the Hade and Gutermuth types. The former is a conical composition valve working on a guide stem carried by the valve box, and opening automatically to afford a free passage of the moving column of water to the discharge end of the pump, and is shown in Fig. 30a. The Gutermuth metallic flip, Fig. 30b, is formed from a long strip of sheet metal, a portion being cabled several times round a spindle, with its inner end held in a slot. The tension of the flip is adjusted by altering the position of the slot. This form of valve has considerable advantages over the ordinary ring type by reason of its lightness and elasticity, being very sensitive and affording a free waterway without any abrupt changes of direction. A speed of 200 revolutions has been reached by pumps using this type.

For still higher speeds mechanically operated valves are necessary, and Fig. 31 shows one unit of a Relier Express pump, where the valves are worked from a wrist-plate driven by an eccentric on the main shaft.

The advantages of high speed are not confined to the reduction in the weight and size of the pump when compared to the slow-speed class, but extend to the discharge, where, with very high lifts, it is of the utmost importance to preserve the constant velocity of outflow which follows from the greater number of revolutions.

(vi) Efficiency.—With reciprocating pumps of the latest types of construction, efficiencies varying from 80 to 86 per cent may easily be obtained, and when the speed of working
is how a well-designed pump may have an efficiency of 90 per cent.

§ (30) Speed Variations.—The method of equalising the variations in the resistance of the pump has already been dealt with. There are, in addition, variations in the external forces actuating the pump which require consideration.

(i.) Direct-drives.—When the pump is steam-driven it may be directly connected to one or more steam cylinders by a common piston-rod,

so that the total steam pressure at any instant is directly transmitted to the water. As it is desirable for the sake of efficiency to use the steam expansively, and therefore with varying pressure, the pressure in the pump will have a considerable range. On the other hand, the resistance of the pump is approximately constant, and as it becomes necessary to introduce some form of compensator whereby sufficient energy is stored during the first portion of the stroke to supply the deficiency which exists in the second, in Fig. 32 let the ordinates measured from OQ to the curve ABOCD be the total resultant pressures on the driving rod during the outward stroke, and ACB the mean or less constant water cylinder pressure: then the shaded area included above AC represents the excess of energy requiring to be stored, and the area included beneath CD the deficiency which must be met in the stroke. The best-known method of doing so is by the use of the Worthington oscillating cylinders, a diagrammatic arrangement of which is shown in the upper portion of the figure. H and L indicate the high and low pressure steam pistons actuating the pump plunger P through the rod R. To the crosshead R on the extension of R are attached rods which operate plungers in the pair of oscillating cylinders placed symmetrically about the centre line at Q and Q'. While the crosshead is moving from H to E, the plungers are displacing water from their respective chambers into a differential accumulator communicating with an air vessel, and work is stored. In travelling from E to R, the outward displacement of the plungers is assisted by the pressure of the accumulator, and work is given out. The work stored and given out during each stroke in the oscillating cylinders is adjusted to balance the variation in energy above and below the mean required in the pump chamber.

(ii.) Flywheel and Shaft drives.—Another class of pumps receive their motion by means of a crank from a shaft on which is mounted a heavy flywheel, and which is operated directly by a steam engine or driven by belt or gearing from an electric motor. Here, the variations of speed and pressure in the prime mover are equalised by the action of a properly designed flywheel. Such pumps are usually constructed with three pump chambers side by side, driven from a common shaft by cranks set at 120° with each other, and are termed three-throw ram plunger pumps. The flow in this class is very continuous, and the type is largely used for boiler feed purposes.

§ (37) Rotary Pumps.—A pump of the rotary class is valuable for use where lack of space prevents the adoption of an ordinary plunger pump. It is valveless, steady in working, and its discharge is practically continuous. It is adapted for working over a large range of speeds at comparatively low heads, with widely varying discharge, and is frequently adopted for irrigation purposes. Its principal disadvantage lies in the difficulty of equalising pressure, leakage past the rotating surface, and the consequent loss of efficiency. This type takes various forms. One consists of a two-part cylindrical casing in which revolves a piston wheel and drum, another employs two piston wheels.

The latter is illustrated in Fig. 33 by the cross-section of a pump with cylindrical wheels, capable of lifting 27,000 gallons of water per minute to a height of over 30 feet for irrigating rice-fields.

The right-hand piston rotates counter-clockwise and drives the water from the lower to the upper part of the casing; the motion of the left-hand piston is clockwise with the same result.
An example of the former is the Kikko pump, shown in Fig. 31, the important feature being the non-contact method of arranging the rotating wheel or displacer and the controller drum to avoid leakage and to minimise wear. The displacer consists of three arms fitted accurately between a segment of the casing and a fixed drum D. It is carried at one end by a disc-keyed to the driving shaft, and at the other the arms are connected by an annular disc which revolves within a recess in the cover. As the displacer revolves the arms fit into recesses in the periphery of the controller drum C, causing it to turn in another segment of the casing. No attempt is made to secure fitted contact between the tips of the displacer arms and the corresponding recesses, as leakage back of the water is sufficiently prevented without it. An over-all mechanical efficiency of 80 per cent for engine and pump has been obtained with this particular form of rotary pump.

§ (38) CENTRIFUGAL PUMPS.—In a centrifugal pump, pressure energy is imparted to a mass of water by the rotation of an impeller wheel. The wheel is formed of a number of curved vanes, and revolves in a suitable casing. When the wheel is charged with water, its rotation produces a forced vortex in the mass of the water contained, with a resulting increase of pressure in a radial direction outward and a tendency to outward flow. If the speed of rotation is sufficiently high the increase in pressure becomes great enough to more than balance the static head against which it operates, and flow takes place. This has the effect of reducing the pressure, thus causing water to rise in the suction pipe and enter the wheel at its center.

When discussing the factors which govern the working of such a pump, certain assumptions are usually made. These are that the pump runs full, and that every particle of water enters the impeller radially without any tangential or swirl velocity, and leaves with a common velocity in a direction tangential to the periphery at every point of discharge.

It is possible to establish a relationship between the total lift of the water H, that is, the difference of head between the surfaces of the vanes, and its rate of delivery with a linear velocity \( v \), if it is assumed that the work done on the pump is just equal to the work done by H, and the efficiency therefore equal to unity.

Let \( Q \) = volume of water dealt with per second in cubic feet,
\( W \) = weight per cubic foot in lbs.,
\( r_1 \) = outer and inner radius of impeller,
\( v_1 \) and \( v_2 \) = velocity of whirl at \( r_1 \) and \( r_2 \),
\( \omega \) = angular velocity of the wheel,
\( U \) = work done on the water passing through per second in ft.-lbs.,
\( g \) = change per second in its angular momentum multiplied by its angular velocity,
\( WQ = g \),
\( U = WQ \),
and since it is assumed that \( w_1 = 0 \), while \( v_2 = \omega \),
\( WQ = \frac{(r_1^2 - r_2^2)}{2} \),
\( WQ = \frac{(r_1^2 - r_2^2)}{2} - \frac{(r_1^2 - r_2^2)}{2} \).

But the work done by the water = \( WQ \), and since this is equal to \( U \), therefore \( WQ = \omega r_2^2 \), \( WQ = \omega r_2^2 \), and \( \omega = \frac{WQ}{r_2^2} \).

All losses due to eddy formation, shock at entrance to or exit from the impeller, and friction in the passages are equivalent to an increase in the head against which pumping has to take place, and must be avoided as far as possible by adopting the form of vanes best suited to the conditions of working.

(1) Shock at Entry.—To avoid shock at entry, the direction of the relative velocity of water and vane must be tangential to the surface of the vane at the inner edge, as shown in Fig. 34 (a), where
\[ \beta = \text{vane angle at entrance}, \]
\[ v_r = \text{peripheral velocity of vane at entry}, \]
\[ f_r = \text{radial velocity of water at entry} = v_{1 \text{tan} \beta}, \]
\[ v_r = \text{relative velocity of water and vane} = \sqrt{v_r^2 + f_r^2}. \]

If variations in the speed of the impeller occur, the relations expressed above will not be maintained, and shock will result. During its travel through the wheel passages the relative velocity of water and vane remains unchanged, but for the less taking place in overcoming the frictional resistance of the sides, and its direction conforms to the curve of the vane.
HYDRAULICS

(i.) Shock at Exit.—At exit the water leaves the impeller at an angle which is the angle of the vanes tip, and its absolute velocity in and radial component \( f_r \) may be determined by a velocity diagram, as in Fig. 38 (b).

If the mean direction of flow in the casing can be taken, as has been assumed, tangential to the impeller circle and its velocity \( v \), the stream discharging from any passage will make with it an angle \( \theta \), and a loss of energy will result, which may be represented by the equation

\[
v^2 - b - \frac{v^2}{2g} \text{ ft.-lbs.}
\]

per lb. of the discharging stream, where \( a \) and \( b \) are constants depending on the angle \( \theta \) and the ratio \( c \) of the volumes of the main and discharging streams at their junction.

(ii.) Loss due to Kinetic Energy of Discharge Flow.—The casing surrounding the impeller is usually designed to include a volute chamber the cross-sectional area of which increases uniformly from A to B, as shown in Fig. 36, and allows a constant velocity of flow \( v \). If free discharge, therefore, is permitted to the upper reservoir at this velocity, a loss equal to the kinetic energy of the discharge stream will occur, and we have a value of \( v^2/2g \) ft.-lbs. per sec. per lb. of water.

(iv.) Friction Losses in Suction and Delivery Pipes.—In addition, the frictional losses due to the resistances of the suction and delivery pipes, and which are of the nature of those already dealt with in pipe flow, require to be allowed for.

It follows, then, that the pressure head \( H_a \) which must be developed in the pump must be greater than the theoretical value \( H \) by an amount sufficient to cover these losses.

(v.) Increase of Pressure Head throughout the Pump.—The steps by which the necessary increase of pressure is obtained may now be examined, as well as any modifikations of the primary design having for their purpose a reduction in the total losses, and therefore of the total pressure necessary.

The natural velocity of a particle of water during its passage through the impeller may be regarded

as made up of two component velocities, one of which is that of the wheel and equal to \( v \); the other parallel to the vanes, having a value \( v_r \), which is the relative velocity of the water and vane. The first corresponds to a motion in a forced vortex with an angular velocity \( \omega \), and the equation of motion for points on the inner and outer periphery of the wheel would be

\[
\begin{align*}
\frac{W}{2g} \omega^2 r^2 &= \frac{W}{2g} v_r^2, \\
\text{Pressure difference} &= \frac{W}{2g} (\omega^2 r^2 - v_r^2) = \frac{W}{2g} (u_r^2 - u^2), \\
\text{The second component corresponds to an outward flow parallel to the vane, of the same volume, with the wheel at rest. In this case} \\
\text{Pressure difference} &= \frac{W}{2g} (\omega^2 r^2 - v_r^2) \\
&= \frac{W}{2g} (u_r^2 - u^2 - \gamma),
\end{align*}
\]

The total difference of pressure \( p_a - p_x \) therefore, between the inner and outer edges of the vanes is given by

\[
\begin{align*}
p_a - p_x &= \frac{W}{2g} u_r^2 + f_2^2 - f_1^2 - \gamma, \\
&= \frac{W}{2g} (u_r^2 - u^2 - \gamma),
\end{align*}
\]

This gain of pressure may be increased if some fraction \( k_2 \) of the kinetic energy \( v_r^2/2g \) ft. lbs. contained in the water as it leaves the impeller is converted into pressure head in the volute chamber, and would equal \( k_2 v_r^2/2g \) ft.

Further, if the discharge takes place from the volute into a pipe of gradually increasing sectional area, the angle of divergence being in the neighborhood of \( 90^\circ \), so that the mean velocity of flow \( v \) in the volute is changed into a discharge pipe velocity of \( u_2 \) ft., the increase of head between the volute and the delivery pipe will be given by

\[
\begin{align*}
p_a - p_x &= \frac{k_2 v_r^2}{2g} \text{ ft.}, \\
W &= \frac{k_2 v_r^2}{2g} \text{ ft.},
\end{align*}
\]

and \( k_2 \) will approximately equal 0.85.

The total difference of pressure through the pump to the delivery pipe will under these conditions equal

\[
\begin{align*}
p_a - p_x &= \frac{W}{2g} (u_r^2 + f_2^2 - f_1^2) - \gamma - k_2 v_r^2 - k_2 v_r^2, \\
&= \frac{W}{2g} (u_r^2 + f_2^2 - f_1^2 - \gamma),
\end{align*}
\]

(vi.) Vortex or Whirlpool Chamber.—Since the efficiency of the pump depends very largely on the conversion of the kinetic energy of the water leaving the impeller into pressure energy, many devices have been tried to secure this end. One of these, devised by Professor James Thomson, is the vortex or whirlpool chamber, circular and concentric with, but of larger diameter than, the impeller, and intruded between the latter and the volute. It is shown in lower half of Fig. 36. The water on leaving the vanes forms approximately a free vortex, and as the velocity diminishes towards the outside of the chamber the pressure increases, assuming there is no eddy losses, then:

\[
\begin{align*}
p_a - p_x &= \frac{f_2^2 - f_1^2}{2g},
\end{align*}
\]
If the ratio between the inlet (front) and the outlet (back) radius of the volute is kept constant, then the ratio of the inlet and outlet radii of the volute is equal to the ratio of the inlet and outlet radii of the impeller. The velocity at the outlet is given by:

\[ v = \frac{\sqrt{2gH}}{\sqrt{R - R_0}} \]

where \( R \) is the inlet radius, \( R_0 \) is the outlet radius, and \( g \) is the gravitational acceleration.

Owing to eddy formation the gain in pressure is only a fraction \( \delta \) of this amount, its numerical value being not accurately known. The effectiveness of the device, if full advantage of it is desired, is marred by the necessity of merely increasing the overall dimensions of the pump.

(vii.) Guide Vanes.—Another device intended to counteract the above-mentioned instability of motion and the formation of eddies on leaving the impeller consists in the introduction of fixed guide vanes or pocket vanes designed to receive without shock the water from the impeller and to direct it by converging passages either into a vortex chamber, as just described, or into the volute. The upper portion of Fig. 36 shows the latter arrangement. The angle of entrance of these vanes should be parallel to the path of the water particles as it leaves the impeller and equal to \( \alpha \) (Fig. 36) if shock is to be avoided. When the pump is required to work under varying conditions the angle should be adjusted to that of maximum efficiency. When this condition is departed from considerably, the result may be that the guides are a source of loss instead of a gain in efficiency. It will be seen from Fig. 35 (b) that the entrance angle is represented by:

\[ \alpha = \tan^{-1} \left( \frac{v_0}{v_0 \cos \gamma} \right) \]

Since the velocity of the water is at its maximum when leaving the impeller, and as only a portion of its kinetic energy can be recovered through proper design and arrangement, it follows that the velocity of discharge should be kept as low as is consistent with maintaining the efficiency of the pump.

Efficiency.—The useful work done by a pump per lb. of water may be taken as represented by \( H + \frac{v_0^2}{2g} + \frac{v_0^2}{2g} \), where \( H \) is the total difference of level between the suction and delivery surfaces; \( \frac{v_0^2}{2g} \) is the equivalent of the friction loss in the suction and delivery pipes; and \( v_0 \) is the velocity in the discharge pipe. The summation of these may be termed the equivalent head \( H_{eq} \). The work which theoretically must be done per lb. of water when all losses are neglected is \( v_0^2/2g \), and to this must be added \( L_{h} \), the sum of all the hydraulic losses, and \( L_m \) that of all the mechanical losses. The efficiency \( \eta \) of the pump is then given by the ratio:

\[ \eta = \frac{H_{eq}}{H_{eq} + \frac{v_0^2}{2g} + \frac{v_0^2}{2g} + L_{h} + L_{m}} \]

Useful work done by the pump per lb. of water passing Total work done on the pump per lb. of water passing and this is equal to

\[ \frac{H_{eq}}{H_{eq} + \frac{v_0^2}{2g} + \frac{v_0^2}{2g} + L_{h} + L_{m}} \]

\[ \eta = \frac{\alpha \left( \frac{v_0^2}{2g} \right) \cos \gamma}{\left( H_{eq} + \frac{v_0^2}{2g} + \frac{v_0^2}{2g} + L_{h} + L_{m} \right) \cos \gamma} \]

So far as this depends on the angle \( \gamma \), it is evident that a reduction of \( \gamma \) will increase the efficiency of the pump, and in addition give to the passages a more uniform cross-section. It must not be forgotten, however, if the head \( H \) to be pumped against remains the same, that any diminution of \( \eta \), effected by a reduction of the angle \( \gamma \), requires an increase of the peripheral speed \( v_0 \) with consequently an increase of frictional loss. In practice the value of \( \gamma \) varies from about 180° to 90°, depending on the purpose for which it is designed and the head against which lift takes place, the maximum permissible value increasing with the working head.

Single impeller pumps are used for heads between 6 and 100 feet and have an actual efficiency of over 75 per cent, and the efficiency is well maintained through a fairly large range of speeds. The limit set in the maximum lift of this pump by the high speed of rotation necessary, and the consequently enormous frictional and eddy losses which occur, have been overcome by the introduction of the

§ (80) COMPOUND MULTIPLE CHAMBER PUMP.

This consists of a series of two or more impellers on the same shaft, each pumping water into the central space of the next adjoining, with the exception of the last, which pumps directly into the delivery pipe as shown in Fig. 37. The impeller diameters and vane angles are made the same for each chamber, and the total lift is equal to the lift of one stage multiplied by the number of stages. Lifts up to 1500 feet are possible by this arrangement. Guide vanes are almost invariably used with the multiple type, as it is essential for efficiency that as far as possible the kinetic energy of discharge from each wheel should be converted into pressure energy before entering the next chamber. In most cases the impellers are mounted in pairs back to back, with the flow in opposite directions, by which mutual the end thrust which occurs in single-inlet impeller wheels is conveniently neutralized. For multiple pumps the impeller vanes are of the enclosed type, thereby reducing the leakage of water between the pump-case and the vanes.
and also the disc friction of rotation. A centrifugal pump before starting is charged with water, a foot-valve being provided in the delivery to prevent the charge being retained. To enable delivery to begin, the conditions of rotation of the wheel must satisfy the equation

$$p_0 - p_1 = \frac{\rho (\frac{r_2^2}{r_1^2} - 1)}{2g} \approx H_0.$$  

§ (40) Other Pumps.—In the types of pumps already considered the operating force has been applied through the medium of a rigidsolid, such as a piston or a revolving wheel. There is, however, an important group where the solid is disengaged with a fluid in direct contact with the water supplies the motive power. This group will now be considered.

§ (41) Pulsometer Steam Pumps.—This pump is closely related in fact, though not in appearance, to the steam reciprocating pump. There is no piston, and the steam which is the working fluid acts directly but alternately on the surface of the water, contained in two pear-shaped chambers east side by side in one piece. An oscillating valve common to both chambers is placed at the junction of their stems, and when the valve admits steam to one chamber it closes to the other. Under pressure of the steam the water with which the chamber has been charged ready for starting is forced through a foot-valve into the delivery pipe. Condensation of the steam remaining takes place, expelled in some cases by the injection of air water spray, and the reduction of pressure which ensues closes the steam inlet valve and the delivery foot-valve while opening the suction valve, and admits water from its inlet opening at the bottom for a fresh charge. The same cycle of operations takes place in the other chamber consequent to the movement of the steam valve, so that delivery in one chamber synchronizes with suction in the other.

The use of this class of pump is limited by practical considerations to lifts below about 100 feet, the most efficient steam pressure being from 45 to 60 lbs. per square inch, though a lift of 170 feet has been attained with steam at 100 lbs. pressure per square inch. The capacity of such pumps based on a lift of 20 feet varies with the size from 1000 to 150,000 gallons per hour. Its efficiency is not high, but it is a useful and cheap appliance for pumping of a temporary kind, and it has the great advantage of not requiring any provision for fixing, being suspended by means of a chain or rope at the desired level.

§ (42) Gas Displacement or Humphrey Gas Pump.—The Humphrey gas pump bears a similar relationship to a gas engine working on the four-stroke cycle as the pulsmeter does to the steam engine. It is a development in the direction of utilizing the force obtained from the combustion of an explosive mixture of gas and air to raise water by direct pressure. The motion of the pump is as follows. At the beginning of the power stroke a charge of gas and air, compressed between the end of the combustion chamber C (Fig. 38) and the column of water contained in the delivery pipe D continues with it, is ignited by electrical spark and expands. By this means the water column is set in motion, acquiring momentum, and part of its contents is discharged. Due to the momentum the expansion is continued until the pressure falls to or below atmospheric, when the water valves W connecting to the suction tank ST and the exhaust valves E open by section offset, the gas inlet valve I being meanwhile locked shut. Its momentum exhausted, the water column oscillates back while the products of combustion are dis-
A set of five pumps of this type, with a total estimated capacity of 180 million gallons per day and a lift of 30 feet, was constructed for the Metropolitan Water Board for use at their Chingford Reservoir. The rate of working approximates to 12 cycles per minute, and in each of the larger units 10 tons of water are delivered per cycle.

§ (43) HYDRAULIC RAM.—The hydraulic ram forms another of this group, the working fluid in this case being water, and is made, as in the gas displacement pump, of the water-hammer principle. A valve-box B (Fig. 39) is placed in communication with a running stream or supply pipe having a small operating head. A waste valve is at open permits of a flow being set up under the influence of this head until the dynamic pressure on the inner side is sufficient to close it. The effect of the sudden closure of the valve is to cause an increase of pressure great enough to open a delivery valve d communicating with a delivery pipe D through an air vessel A. A portion of the water which escapes is used to compress the air in A, and a portion passes up the delivery pipe before the momentum of the column is absorbed. The pressure in the air vessel reacting initiates an impulse in the opposite direction, the delivery valve closes, and the reduction of pressure in the valve-box which results enables the waste valve to again open. The normal flow resumes with the next oscillation, increasing until the dynamic pressure once more closes the valve. By this method a low-head large flow is enabled to lift a smaller flow through a large head.

The efficiency of the ram depends on what is considered the effective lift of the discharge Q. If it is assumed to be the difference between the levels of the supply intake H and the surface of the storage tank h, then the useful work done is represented by \( Q(h - H) \), while the work done on the ram equals \( q' \cdot H \) and \( q = Q(h - H)/p'H \), where \( q' = \) water flowing past waste valve.

If, however, the useful lift is regarded as \( h' \), then

\[
Q \cdot h' = \text{the useful work done by the ram, and}
\]

\[
q' = Q \cdot h/(Q + q') H
\]

The values obtained on the first assumption are consistently lower than with the second, but even on that basis the efficiencies where the delivery head does not exceed four times the supply head may be as high as 75 per cent. For a given supply head the efficiency of the ram falls off very rapidly with an increase of the delivery head ratio above the value just given. For small diameters of supply pipe this type of pump gives excellent results, but with larger sizes trouble is apt to arise through excessive shock when the valve is suddenly closed. To obviate this sometimes an air dashpot is fitted to the waste valve spindle, but while effective for this purpose it has the disadvantage of lowering the efficiency of the pump, since closed, allowing leakage past the valve at the time when the velocity of the waste water is at its maximum, means a larger proportional loss of energy, compared to the whole kinetic energy of the water column. The introduction of mechanical regulation of the valves enables this type to be successfully applied to the pumping of water on a much larger scale and against greater heights than is possible where automatic valves are used.

§ (44) JET PUMP.—The working fluid in the jet pump is also water, but the principle of working is quite different. It is operated by the conversion of the high-pressure energy of a water supply into kinetic energy, and as the velocity is increased the pressure diminishes until it may be that a pressure loss than atmospheric is reached. This is effected in the passage of the water through a converging nozzle N (Fig. 40), which is surrounded by a concentric chamber C communicating with the lower reservoir by means of a suction pipe. The reduction of pressure at the face of the nozzle due to the issuing jet induces flow in this pipe which combines with the water from the jet and is carried forward into a diverging portion of the discharge pipe D. Thence the dynamic pressure is partly reconverted into pressure energy sufficient to maintain flow against
HYDRAULICS

the discharge head. The energy contained per lb. of the combined streams is

\[ p_d \sqrt{\frac{W_1 + W_2}{2g}} \]

and must be equal to \( H_2 \), the losses between the two contacts and the delivery surface, where \( p_d, W_1, W_2 \) and \( H_2 \) are the pressure, velocity, and head in the delivery pipe.

The square of the velocity necessary for delivery varies as \( H_2 \) and is independent of the suction head \( H_1 \), and as the loss of energy is proportional to \( v^2 \), it will also be proportional to \( H_2 \). For a given lift, therefore, the suction head should be made as great as possible.

The useful work done by the pump

\[ \eta = \frac{Q_2 (H_2 + l_s)}{Q_1 (H_2 - l_s)} \]

where \( Q_1 \) and \( Q_2 \) are the quantities from suction and pressure supply respectively, and \( l_s \) is the high pressure head.

The actual values of \( \eta \) reached do not exceed 30 per cent, and are usually round about 25 per cent.

This low efficiency may be increased by substituting for the single-stage impact between the streams a multi-stage arrangement. By this means the loss of energy due to shock when the high velocity jet meets the low velocity flow is substantially reduced, and the efficiency may be raised to 33 per cent.

When the fluid used for the high-pressure jet is steam the injector becomes the well-known locomotive type associated originally with the name of Clift and largely used for boiler feed purposes.

Another modification may be mentioned where the above process is reversed and a high-pressure water jet is used to draw away steam from, and to maintain a vacuum in, the exhaust chamber of a steam engine. This combination is termed an Ejector Condenser.

§ 45 (45) AIR-LIFT PUMP.—The method of raising water on the suction principle is another example still of the direct application of a working fluid, and has found considerable favour during recent years especially as applied to artesian wells. It consists primarily of two pipes, one (A, Fig. 41) having its lower end submerged in the liquid to be raised and its upper end arranged to discharge into a reservoir at the required height, and the other (a) for conveying air from a compressor to a nozzle \( n \), situated in the submerged opening of the rising main. The air is diffused through the water in the uptake pipe and forms a mixture having a low specific gravity. The pressure of the heavier fluid in the surrounding casing forces the lighter mixture above the supply level and out of the top of the delivery pipe. The difference of pressure thus obtained determines the height to which the water can be lifted, and will vary with the depth of submersion of the pipe. A sketch of three alternative forms of the arrangement is shown in Fig. 41.

The air tube may be lifted either concentric internally or externally to the uptake pipe or parallel to it. To the first (1) of these methods the objection is raised that it increases the frictional resistance to the water flow and consequently lowers the efficiency, but it is very convenient in the case of a small bore hole. The second (2) admits of more effective air distribution which is an essential in this type of pump, but where the well is of large diameter the system of parallel pipe (3) has the advantage of being most readily accessible and very flexible. Broadly speaking, the least pressure of air that will give continuous flow is the proper pressure to use. Its approximate value is 35 lb. per square inch for each foot of lift from the surface of the water.

The efficiency of this type of pump is low, and reckoned as the ratio of water H.P. to the compressor cylinder L.H.P. does not exceed 45 per cent. If calculated from the indicated power of the prime mover not more than 30 per cent would probably be registered. Against this low efficiency must be set the simplicity of the mechanism of the pump, its ease in setting up and the immunity it possesses from the scoring and chocking effects of sand or siltstone. These latter considerations probably account for the revival of interest in this ingenious type of pump.

III. THE APPLICATION OF WATER POWER TO INDUSTRIAL PURPOSES

§ 46 (46) The Energy of Stored Water.—It has been seen how supplies of water can be
collected from natural sources and stored, or made available by artificial means for the purpose of distribution to satisfy the requirements of the consumer. It is with the means taken to utilise the power latent in a supply that it is now proposed to deal.

The capacity for work of a store of water may be made the means of furnishing working forces during the descent of the water from a higher to a lower level, through a properly designed machine, whereby a steady motion of that machine may be maintained against various resisting forces. If \( Q \) be the quantity of water in cubic feet per second available, \( H \) the total available head in feet, and \( W \) the weight of 1 cubic ft. of water, then the Capacity for work or Potential Energy of the water = \( QWH \) ft-lbs., per second, and this is equivalent to \( H \) ft-lbs., per second per lb. of water. The ratio of the useful work done by the water in its descent to the potential energy or capacity for work latent in the water when stored is termed the efficiency of the machine. Machines designed to utilise this potential energy are called Hydraulic Motors or Primo Movers. The work done is due entirely to the loss of head of the water during its descent, but the method of applying the energy will depend on the type of motor selected. In general, it consists of a wheel which is caused to rotate either by the weight of the descending water or by the dynamic pressure arising from a change in direction and velocity of the moving stream. Piston engines, where the water does work in virtue of its static pressure only, form, however, an important class.

When the water enters the wheel at one point only of the circumference the machine is called a Water-wheel; when it enters the entire circumference more or less simultaneously it is called a turbine. For convenience it is proposed to classify the various types into the three main divisions: (a) water-wheels, (b) turbines, and (c) pressure engines, and to consider them in that order.

(i) Water-wheels.—In this division the working force is obtained:
   (i) By the weight of the water, producing rotation as in the ovoidot and breast wheels;
   (ii) By utilising the kinetic energy of a moving stream as in undershot wheels;
   (iii) From the impact of a high velocity jet of water as in the Pelton wheel.

(ii) Overhead Wheels.—The construction of this type of motor, which was very general for small powers with heads ranging from 15 to 50 feet, is very simple and is illustrated in Fig. 42.

The water is supplied, as near the highest point of the wheel as possible, to a series of buckets formed of shrivelled vanes, and escapes when the outer part of the bucket is horizontal, which occurs before the lowest position of the bucket is reached. The useful head is less than the theoretical head \( H \) (a) by an amount which depends on this discharge position, and (b) by the amount required to supply the kinetic energy of the stream. If \( h \) is equal to the total head thus absorbed, then \( H - h \) will represent that available for useful work and the efficiency possible is \( \frac{1}{2} (H - h) \).

Maximum efficiency is obtained when the peripheral velocity of the wheel is equal to one-half the velocity of the inflow water. To prevent loss by shock at entrance to the buckets the vane angle at the tip should be parallel to the relative motion of the water and vane there. This angle is usually arranged to make 25° to 30° with the tangent to the circumference, and as a consequence the bucket retains water for a vertical distance nearly equal to \( \frac{1}{2} \) of the wheel diameter. When working under unsuitable condition efficiencies up to 80 per cent may be obtained.

(ii) Breast Wheel.—Where the working head ranges between 6 feet and 15 feet the supply is admitted to the buckets at some point situated in the breast of the wheel (Fig. 43). Any loss of head due to the premature escape of the water from the buckets becomes proportionately greater, since the head is less, and is prevented by the building of a breast-work of masonry with a minimum clearance between it and the wheel. Precautions similar to those taken in the overshot type are required to prevent shock at entry, and special provision is made of air vents at the inner circumference of the wheel to let the air out as the water rushes into the buckets. Under favourable circumstances an efficiency of 85 per cent may be reached.

The Stagibian wheel is a form of breast wheel in which the bucket is replaced by long flat vanes, tangential to a circle concentric...
with the wheel and making an angle at the outer circumference parallel to the relative velocity of water and vanes as shown in Fig. 41. The velocity of rotation is proportional to the flow, and the wheel is therefore capable of dealing with large variations of supply. Any increase of the load, however, has the effect of slowing down the wheel and reducing the supply just at the time when an increase of energy is most required. Efficiencies up to 90 per cent have been attained by this form.

![Fig. 41](image)

(3.) Undershoot and Pelton Wheels.—In the undershot wheel adopted for low heads of 3 feet and water, work is done by the action of a moving stream impinging against a series of radial vanes set round the circumference of the wheel, the change of momentum of the water being a measure of the force applied. The wheel dips into the stream, the tips of the vanes just clearing the bottom of the channel. A maximum efficiency of 90 per cent is obtained with a peripheral velocity of wheel on-half the velocity of the stream, but in practice the efficiency does not reach more than 35 per cent.

A modification of this wheel is the Pelton wheel (Fig. 45), where the vanes instead of being radial are inclined backward to make an angle at the tips with the circumference. By this means loss at entrance due to shock is avoided, while if properly designed, the loss of energy in the discharge stream is reduced.

If \( v_1 \) = the absolute velocity of water at entrance, \( \alpha \) = the angle which it makes with the tangent to the circumference at the tip, \( v_2 \) = peripheral velocity of vane tips.
